

# A Banach space with basis constant $> 1$ .

PER ENFLO

University of Stockholm and University of California at Berkeley

If a Banach space has a Schauder basis  $\beta$ , then  $\beta_K = \sup_{x,n} \|\sum_{i=1}^n a_i e^i\| / \|x\|$  exists, where  $x = \sum_{i=1}^{\infty} a_i e^i$ . Inf  $\beta_K$  taken over all  $\beta$  is called the basis constant of the Banach space. It is obvious that if the Banach space  $B$  has the basis constant  $p$ , then every finite-dimensional subspace  $C$  of  $B$  can be approximated by subspaces  $D_n$  of  $B$  – by approximating a set of basis vectors of  $C$  with vectors of finite expansions in some basis – such that each  $D_n$  can be embedded into a finite-dimensional subspace  $E_n$  of  $B$ , onto which there is a projection from  $B$  of norm arbitrarily close to  $p$ .

In this paper we construct a separable infinite-dimensional Banach space  $B$  with a two-dimensional subspace  $C_1$  with the following properties: There is a  $p > 1$  such that, if  $D$  is a two-dimensional subspace of  $B$  sufficiently close to  $C_1$  and  $E$  is a finite-dimensional subspace of  $B$  containing  $D$ , then there is no projection from  $B$  onto  $E$  of norm  $\leq p$ . Thus the basis constant of this Banach space is  $\geq p$ . This seems to be by now the strongest result in negative direction on the well-known basis problem. The previously strongest result seems to be Gurarii's example of a Banach space where  $\beta_K > 1$  for every  $\beta$ . (See Singer [1] pp. 218–42.)

We now start by giving a general and somewhat unprecise description of the ideas behind the construction and of the problems we meet. We consider a two-dimensional subspace  $C_1$  of  $l_{\infty}(I)$ , where  $I$  is the set of pairs of positive integers. We assume that the projection constant of  $C_1$  is  $> 1$ . Now our first ambition will be to embed  $C_1$  in a larger space  $E_1$ , such that there is no projection of norm close to 1 from  $E_1$  onto spaces close to  $C_1$  and such that no subspace  $C_2$  of  $E_1$  containing a subspace of  $E_1$  sufficiently close to  $C_1$  has a projection constant near to 1. However, if we try to do this we have to get control of quite many linear spaces. In order to describe how we obtain the necessary simplifications, we give now a description of the way we estimate norms of projections.
