# On the Approximability of Reachability-Preserving Network Orientations 

Michael Elberfeld, Vineet Bafna, Iftah Gamzu, Alexander Medvedorsky, Danny Segev, Dana Silverbush, Uri Zwick, and Roded Sharan

#### Abstract

We introduce a graph-orientation problem arising in the study of biological networks. Given an undirected graph and a list of ordered source-target vertex pairs, the goal is to orient the graph such that a maximum number of pairs admit a directed source-to-target path. We study the complexity and approximability of this problem. We show that the problem is NP-hard even on star graphs and hard to approximate to within some constant factor. On the positive side, we provide an $\Omega(\log \log n / \log n)$ factor approximation algorithm for the problem on $n$-vertex graphs. We further show that for any instance of the problem there exists an orientation of the input graph that satisfies a logarithmic fraction of all pairs and that this bound is tight up to a constant factor. Our techniques also lead to constant-factor approximation algorithms for some restricted variants of the problem.

## I. Introduction

A major role of a protein-protein interaction (PPI) network is to transmit signals within the cell in response to genetic and environmental cues. Technologies for
measuring PPIs such as yeast two-hybrid [Fields 05] and co-immunoprecipitation [Gavin et al. 02] are unable to provide information on the direction in which the signal flows. Such information can be inferred from indirect, causal information on cellular events. One such source of information is perturbation experiments, in which a gene is perturbed (cause) and as a result, other genes change their expression levels (effects).

In graph-theoretic terms, one is given an undirected graph and a list of sourcetarget pairs that represent the experimentally observed cause-effect pairs. The goal is to predict an orientation of the graph, i.e., a directed graph on the same vertex set that contains a single directed version of every undirected edge, so that for a maximum number of pairs, the target is reachable from the source. We study the complexity of approximating the resulting MAXIMUM-GRAPH-ORIENTATION problem.

The algorithmic research on graph orientations that preserve reachability initially focused on producing strongly connected orientations. It started with [Robbins 30], in which the author was motivated by applications in street network design. He showed that an undirected graph has a strongly connected orientation if and only if it has no bridge edge. In [Hakimi et al. 97], a polynomial algorithm is presented for the problem of orienting an undirected graph $G=(V, E)$ to preserve reachability for a maximum number of all vertex pairs (i.e., from the set $V \times V$ ). The problem we study is a generalization of the latter, for it considers every subset of pairs. We refer to the textbook [Bang-Jensen and Gutin 08] for a comprehensive discussion of various graph-orientation problems.

The authors of [Yeang et al. 04] were the first to use perturbation experiments to annotate protein networks. They proposed a probabilistic model and an accompanying inference approach to predict edge directions and signs of activation and repression from cause effect data. In [Ourfali et al. 07] can be found an integer linear program formulation for the problem of inferring edge signs that maximize the expected number of explained cause effect pairs. In [Gitter et al. 11], SATISFIABILITY-based approximations are used to tackle the orientation problem. The main caveat of all these approaches is that they depend on enumerating all possible paths between a pair of genes, and hence they are limited to paths of very short length (3 for the first two works and 5 for the latter). Finally, [Dorn et al. 11] studies the complexity of solving the orientation problem with respect to structural parameters that measure how often vertices (or edges) are used by source-to-target paths.

In this paper we show that the MAXIMUM-GRAPH-ORIENTATION problem can be reduced to the same problem on instances in which the input graph is a tree. We focus on the latter problem, called maximum-tree-orientation. We show that it is NP-hard and hard to approximate to within a factor of $12 / 13$. On the
positive side, we show that for an $n$-vertex tree, the problem can be approximated to within a factor of $\Omega(\log \log n / \log n)$.

We also study combinatorial properties of graph orientations, showing that for every undirected graph and collection of source-target vertex pairs, there exists an orientation that satisfies a logarithmic fraction of the pairs and that this bound is tight up to a constant factor. We also present algorithms with constant approximation ratios for restricted instances of MAXIMUM-TREE-ORIENTATION. In particular, we provide a constant approximation algorithm for instances in which the distance between source and target vertices is bounded by a constant.

The paper is organized as follows: In Section 2, we define the graph-orientation problem that we consider and provide hardness results. In Section 3, we present combinatorial bounds on the number of pairs that can be satisfied in different orientation instances. In Section 4, we provide a constant-factor approximation algorithm for the restriction of maximum-tree-orientation, where the end vertices of pairs are connected by short paths. In Section 5, we present a sublogarithmic approximation algorithm for the general case.

## 2. Preliminaries

Let $G=(V, E)$ be an undirected graph on $n$ vertices. We use $V(G)$ and $E(G)$ to refer to its sets $V$ of vertices and $E$ of edges, respectively. The graph $G$ is a tree if it is connected and has no cycles. An orientation of $G$ is an assignment of directions to the edges of $G$ such that each edge is assigned a single direction.

Given a source vertex $s \in V(G)$ and a target vertex $t \in V(G)$, we say that $t$ is reachable from $s$ if there exists a path in $G$ from $s$ to $t$. In this case, we also say that $G$ satisfies the source-target vertex pair $(s, t)$. The problem we study is formally defined as follows:

Problem 2.I. (MAXIMUM-GRAPH-ORIENTATION.)
Input: An undirected graph $G=(V, E)$ and a multiset of source-target vertex pairs $P$ from $G$.

Output: An orientation $G^{\prime}$ of $G$ that satisfies a maximum number of pairs from $P$.

A tuple $(G, P)$ of an undirected graph $G$ and a multiset of source-target vertex pairs $P$ from $G$ is called an orientation instance; $|P|$ denotes the number of pairs in the multiset $P$.

Lemma 2.2. There exists a linear-time algorithm that given an orientation instance $\left(G, P_{G}\right)$, computes an orientation instance $\left(T, P_{T}\right)$ with tree $T$ such that for every $k \in \mathbb{N}$, there exists an orientation $G^{\prime}$ of $G$ that satisfies $k$ pairs from $P_{G}$ if and only if there exists an orientation $T^{\prime}$ of $T$ that satisfies $k$ pairs from $P_{T}$.

Proof. The algorithm computes the tree $T$ of $G$ 's two-edge connected components. Vertex pairs $P_{G}$ in $G$ are transformed into vertex pairs $P_{T}$ in $T$ by the following rule: For every pair $(s, t) \in P_{G}$ we construct a pair $\left(C, C^{\prime}\right)$, where $C$ and $C^{\prime}$ are the two-edge connected components of $G$ that contain $s$ and $t$, respectively. Computing the tree of two-edge connected components can be done in linear time, as shown in [Tarjan 72, Tarjan 74]; the transformation of the pairs can also be done in linear time.

An orientation $G^{\prime}$ of $G$ translates into an orientation $T^{\prime}$ of $T$ by taking the oriented versions of the bridge edges between two-edge connected components. For every vertex pair $(s, t) \in P_{G}$ that is satisfied in $G^{\prime}$, the corresponding pair of components $\left(C, C^{\prime}\right)$ is also satisfied in $T^{\prime}$. Conversely, consider an orientation $T^{\prime}$ of $T$. We will use the orientations from the edges of $T$ for the bridge edges between the two-edge connected components in $G$ and a strongly connected orientation for each two-edge connected component. Such orientations exist by a theorem in [Robbins 30], and they satisfy every pair whose source and target vertices lie in the same two-edge connected component.

By Lemma 2.2, it is sufficient to solve the maximum-Graph-orientation problem for orientation instances $(T, P)$ with $T$ being a tree. This results in the formal maximum-tree-orientation problem. In the following, we prove NPhardness for an even more restricted problem variant in which the input graph is a star.

Theorem 2.3. The MAXIMUM-TREE-ORIENTATION problem is NP-hard to approximate to within a factor of $12 / 13$.

Proof. We reduce from the maximum-directed-cut problem [Kann et al. 96], where we are given a directed graph $G$ and wish to find a subset $A \subseteq V(G)$ such that a maximum number of edges cross from $A$ to $V(G) \backslash A$ in $G$.

For the reduction, we map a directed graph $G$ to an orientation instance $(S, P)$ with $S$ being a star graph in the following way: We set $V(S)=V(G) \cup\left\{v_{c}\right\}$, where $v_{c}$ is a vertex not in $V(S)$ that will be the vertex in the center of $S$. For every vertex $v \in V(G)$, we insert an undirected edge between $v$ and $v_{c}$ into the edge set $E(S)$. We define $P$ to be the set of directed edges of $G$. We claim that for every $k \in \mathbb{N}$, there exists a set $A \subseteq V(G)$ such that at least $k$ edges from
$E(G)$ go from $A$ to $V(G) \backslash A$ if and only if there exists an orientation $S^{\prime}$ of $S$ that satisfies at least $k$ pairs from $P$.
For the "only if" direction, consider a set $A \subseteq V(G)$ with $k$ crossing edges. For all $v \in A$, orient the edge between $v$ and $v_{c}$ from $v$ toward $v_{c}$. All other edges are oriented away from $v_{c}$. Every pair with a corresponding edge that goes from $A$ to $V(G) \backslash A$ is satisfied by this orientation.

For the "if" direction, let $S^{\prime}$ be an orientation of $S$ that satisfies $k$ pairs from $P$. Let $A$ be the set of vertices from $V(S) \backslash\left\{v_{c}\right\}$ whose incident edges are oriented toward $v_{c}$. Pairs that are satisfied in $S^{\prime}$ have their source vertices in the set $A$ and their target vertices in the set $V(S) \backslash A$. To each of these pairs corresponds an edge that goes from $A$ to $V(G) \backslash A$ in $G$.

Since MAXIMUM-DIRECTED-CUT is NP-hard to approximate to within a factor of $12 / 13$ [Håstad 01] and the reduction is approximation-preserving, the claim follows.

The Maximum-Tree-orientation problem is also NP-hard when restricted to complete binary trees [Medvedovsky et al. 08] or caterpillar trees of degree at most 3, like $\overbrace{}^{\square-\infty}$ [Medvedovsky 09]. In contrast, on path graphs (graphs like $\infty-\infty$ it can be solved in polynomial time by a dynamic programming algorithm [Medvedovsky et al. 08, Dorn et al. 11].

## 3. Combinatorial Logarithmic Bounds

In this section we prove bounds on the number of pairs that can be satisfied in various orientation instances. We first introduce the concept of covers and show that orientation instances with restricted covers admit orientations satisfying a constant fraction of the pairs. Then we turn to general orientation instances and show that they always admit an orientation satisfying a logarithmic fraction of their pairs and that this is tight up to a constant factor.

## 3.I. Constant Factor Bounds

In the following we will consider tree instances, and instead of orienting edges individually, we partition the input tree into subtrees and orient all edges of a subtree at the same time in a consistent direction.

A cover for $T$ is a tuple $(\mathcal{T}, \mathcal{W})$ that consists of (1) a class $\mathcal{T}=\left\{T_{1}, \ldots, T_{l}\right\}$ of induced subtrees of $T$ where every $T_{i}$ is connected and $E\left(T_{1}\right), \ldots, E\left(T_{l}\right)$ is a partition of $E$ and (2) a collection of vertices $\mathcal{W}=\left\{w_{1}, \ldots, w_{l}\right\}$ with $w_{i} \in V\left(T_{i}\right)$ for every $i \in\{1, \ldots, l\}$. The size of the cover is $|\mathcal{T}|=|\mathcal{W}|$. For every subtree
$T_{i}$, we consider two orientations: the orientation $T_{i}^{\text {receiver }}$, where all edges are oriented toward the vertex $w_{i}$ (i.e., every edge is oriented toward its incident vertex nearest to $w_{i}$ ), and the orientation $T_{i}^{\text {sender }}$, where all edges are oriented in the opposite direction. We consider the collection of orientations of $T$ that are produced by choosing, for every subtree $T_{i}$, one of $T_{i}^{\text {receiver }}$ and $T_{i}^{\text {sender }}$ and combining them to an orientation for $T$. For a cover of size $l$, this collection contains $2^{l}$ orientations. For an orientation instance $(T, P)$, we define a pair cover as a cover $(\mathcal{T}, \mathcal{W})$ for $T$ such that for every pair $(s, t) \in P$, there exists an orientation in the cover that satisfies $(s, t)$. The crossing number of a pair cover is the maximum number of subtrees whose edges are used by a pair on the path from its source to its target vertex.

Lemma 3.I. Let $(T, P)$ be an orientation instance admitting a pair cover $(\mathcal{T}, \mathcal{W})$ with crossing number $c$. Then there exists an orientation $T^{\prime}$ of $T$ that satisfies at least $|P| / 2^{c}$ pairs from $P$.

Proof. We consider a uniform probability distribution on the collection of orientations of $T$ that can be constructed with respect to $(\mathcal{T}, \mathcal{W})$. Note that it is equivalent to say that we choose, for every subtree $T_{i} \in \mathcal{T}$, with probabilities $1 / 2$ the orientation $T_{i}^{\text {receiver }}$ or the orientation $T_{i}^{\text {sender }}$. For every pair $(s, t)$, we consider a random variable $X_{(s, t)}$ that is evaluated to 1 if the particular orientation satisfies $(s, t)$ and 0 otherwise. The satisfaction of a pair depends only on the orientations of the at most $c$ subtrees whose edges are used by its source-to-target path. Thus every pair is satisfied with probability at least $1 / 2^{c}$ (in particular, $\left.E\left[X_{(s, t)}\right] \geq 1 / 2^{c}\right)$. Let us denote by $X$ the random variable that equals the total number of pairs that are satisfied in an orientation. By linearity of expectation, $E[X]=\sum_{(s, t) \in P} E\left[X_{(s, t)}\right] \geq|P| / 2^{c}$. Thus, there must exist an orientation, as desired.

Since the conditional expectation with respect to partial orientations of the tree can be computed in polynomial time by deleting all unsatisfied pairs from $P$, contracting the oriented edges, and computing the expectation value for the remaining instance, we can apply the method of conditional expectations [Alon and Spencer 00] to construct a deterministic polynomial-time algorithm that produces the orientations from Lemma 3.1.

In some restricted cases, the input trees admit the polynomial-time construction of pair covers with small crossing numbers, and hence orientations satisfying a constant fraction of all input pairs. This leads to the following bounds for star and caterpillar graphs:

(a)

(b)

Figure I. (a) A star tree and (b) a caterpillar tree along with their pair covers as constructed in the proof of Lemma 3.2. The cover subtrees from $\mathcal{T}$ are depicted with gray background bars; the vertices from $\mathcal{W}$ are filled in black.

Lemma 3.2. The following two properties hold:

1. Let $(S, P)$ be an orientation instance with a star graph $S$. Then there exists a polynomial-time computable orientation $S^{\prime \prime}$ of $S$ that satisfies at least $|P| / 4$ pairs from $P$.
2. Let $(C, P)$ be an orientation instance with a caterpillar graph $C$. Then there exists a polynomial-time computable orientation $C^{\prime}$ of $C$ that satisfies at least $|P| / 8$ pairs from $P$.

Proof. To prove the lemma, we show that orientation instances with star graphs and caterpillar graphs admit polynomial-time computable pair covers with respective crossing numbers 2 and 3 . Examples of the constructed pair covers are given in Figure 1.

We start with orientation instances $(S, P)$, where $S$ is a star with center node $v_{c}$. We define the pair cover $(\mathcal{T}, \mathcal{W})$ to be the collection of all edges from $E(S)$ together with $w_{i}=v_{c}$ for all $i \in\{1, \ldots,|E(S)|\}$. It can be computed in polynomial time for a given star graph, and since it has crossing number at most 2, applying Lemma 3.1 and the subsequent derandomization proves the claim.

Recall that a caterpillar graph is made up of a backbone path and edges attached to that path. For caterpillars, we construct a pair cover $(\mathcal{T}, \mathcal{W})$ by taking the backbone path and the edges attached to it into the collection $\mathcal{T}$. Note that all graphs in $\mathcal{T}$ are paths. For each of them we use any end vertex as $w_{i}$. This cover is polynomial-time computable and has crossing number at most 3. Similarly to the star graph case, the claim follows.

Figure 1 shows examples of the pair covers constructed in the proof of Lemma 3.2.

We note that MAXIMUM-TREE-ORIENTATION on star graphs reduces to maximum-directed-cut by the following two-step reduction: Without loss of generality, we start with an orientation instance $(S, P)$ with a center vertex $v_{c}$
where each pair has distinct end vertices. First, consider pairs $(s, t)$ for which one of $s$ and $t$ equals $v_{c}$. Delete $(s, t)$ from $P$, insert a new vertex $v_{(s, t)}$ into $V(S)$ that is connected to $v_{c}$, and insert a copy of $(s, t)$ into $P$, where the vertex equal to $v_{c}$ is replaced by $v_{(s, t)}$. This does not change the size of an optimal orientation, and no pair contains the center vertex. Next, consider the new instance ( $S^{\prime}, P^{\prime}$ ) from the first step, and construct the graph $\left(V\left(S^{\prime}\right), P^{\prime}\right)$. Similarly to the proof of Theorem 2.3, every optimal orientation for $\left(S^{\prime}, P^{\prime}\right)$ can be turned into an optimal cut for $\left(V\left(S^{\prime}\right), P^{\prime}\right)$, and vice versa. It follows that the orientation problem on stars admits a 0.874 approximation using the corresponding approximation algorithm for maximum-directed-cut [Lewin et al. 06].

### 3.2. Logarithmic Factor Bounds

Lemma 3.3. Let $(T, P)$ be an orientation instance with a tree $T$. There exists an orientation $T^{\prime}$ of $T$ that satisfies at least $|P| /(4\lceil\log n\rceil)$ pairs from $P$.

Proof. We partition the multiset $P$ into $\lceil\log n\rceil$ multisets $P_{1}, \ldots, P_{\lceil\log n\rceil}$ such that every orientation instance ( $T, P_{i}$ ) admits an orientation satisfying at least $\left|P_{i}\right| / 4$ of the pairs in $P_{i}$. Taking the instance with the largest set $P_{i}$ and an orientation that satisfies at least $1 / 4$ of its pairs results in an orientation that satisfies $1 /(4\lceil\log n\rceil)$ of all pairs.

Let $v \in V(T)$ be a vertex whose removal breaks the tree into components of size at most $\lceil|V(T)| / 2\rceil$; such a centroid vertex always exists in trees and can be found in polynomial time [Frederickson and Johnson 80]. Let $P_{1}$ be the pairs from $P$ with source-to-target paths crossing the vertex $v$ and consider the orientation instance $\left(T, P_{1}\right)$. We construct a pair cover $\left(\mathcal{T}_{1}, \mathcal{W}_{1}\right)$ for $\left(T, P_{1}\right)$, where $\mathcal{T}$ consists of all subtrees rooted at $v$, and vertices in $\mathcal{W}$ equal $v$. This pair cover has crossing number 2. Thus, by Lemma 3.1, there exists an orientation satisfying at least $1 / 4$ of the pairs $P_{1}$.

Next, let $F$ be the forest that arises by deleting $v$ from $T$. Note that the path of every pair from $P \backslash P_{1}$ lies completely inside one of the trees from this forest. We consider centroid vertices for all trees of $F$ and let $P_{2}$ be the multiset of pairs from $P \backslash P_{1}$ that cross any of these vertices. We use the same construction of pair covers as above for every tree of the forest, and merge the covers to obtain a pair cover with crossing number 2 for the orientation instance ( $T, P_{2}$ ). It witnesses that there exists an orientation $T^{\prime}$ of $T$ satisfying at least $1 / 4$ of the pairs from $P_{2}$. We proceed recursively by breaking $F$ into subforests using centroid vertices. This produces $\lceil\log n\rceil$ orientation instances $\left(T, P_{1}\right), \ldots,\left(T, P_{\lceil\log n\rceil}\right)$, each admitting an orientation that satisfies at least $1 / 4$ of its pairs using the same arguments.

The following lemma shows that the logarithmic bound from Lemma 3.3 is tight up to a constant factor. We refer to Section 7 for its proof.

Lemma 3.4. For every $r \in \mathbb{N}$, there exists an orientation instance ( $T_{r}, P_{r}$ ) with $\left|V\left(T_{r}\right)\right|=2^{r+1}-1$ and $\left|P_{r}\right|=2 r 4^{r-1}$ such that every orientation of $T_{r}$ satisfies at most $\left(4^{r}-1\right) / 3$ pairs. This is at most $2 /(3 r)$ of all pairs, which is logarithmic in the size of $T_{r}^{v}$

## 4. Constant-Factor Approximation for Pairs of Bounded Distance

In this section we consider tree-orientation instances $(T, P)$ for which the distance between the source and target vertices of each pair is at most a constant $d \in \mathbb{N}$. We prove that such instances always admit orientations satisfying at least $1 /(4 d)$ of the input.

Lemma 4.I. Let $d \in \mathbb{N}$. Let $(T, P)$ be an orientation instance with a tree $T$ such that for every pair $(s, t) \in P$, the path from $s$ to $t$ in $T$ has length at most $d$. Then there exists an orientation $T^{\prime}$ of $T$ that satisfies at least $|P| /(4 d)$ pairs from $P$.

Proof. Choose any vertex $r \in V(T)$ and consider, for every pair $(s, t) \in P$, the unique vertex $v_{(s, t)}$ from the $s$-to- $t$ path that has shortest distance to $r$. We partition the pairs $P$ into $d$ multisets $P_{0}, \ldots, P_{d-1}$ as follows: A pair $(s, t) \in P$ lies in $P_{i}$ if and only if $i \equiv d_{(s, t)} \bmod d$, where $d_{(s, t)}$ is the distance between $r$ and $v_{(s, t)}$. An example instance and its partition are depicted in Figure 2.

We prove that for every orientation instance $\left(T, P_{i}\right)$, there exists an orientation satisfying at least $\left|P_{i}\right| / 4$ pairs. Taking such an orientation for the largest multiset $P_{i}$ results in an orientation that satisfies at least $|P| /(4 d)$ pairs. We use Lemma 3.1 and the following pair cover with crossing number 2: For an instance ( $T, P_{i}$ ), we produce $\mathcal{T}$ by splitting $T$ at every vertex $v$ whose distance from $r$ modulo $d$ is $i$. For every subtree $T_{j}$ from $\mathcal{T}$, its vertex $w_{j}$ is the vertex from $V\left(T_{j}\right)$ with lowest distance to $r$ in $T$. Since the distance between the source and target vertices of each pair is at most $d$, the path of every pair lies in at most two subtrees from $\mathcal{T}$. Moreover, every pair in $P_{i}$ can be satisfied by an orientation with respect to this pair cover: Either it lies completely inside a subtree $T_{j}$ and one of its end vertices is $w_{j}$, or it lies in two subtrees $T_{j}$ and $T_{k}$ with $w_{j}=w_{k}$.

Let $(T, P)$ be an orientation instance with tree $T$. The conflict graph of $(T, P)$, denoted by $C_{(T, P)}$, is the undirected graph with vertex set $P$ and an edge between two pairs $p_{1}=\left(s_{1}, t_{1}\right) \in P$ and $p_{2}=\left(s_{2}, t_{2}\right) \in P$ if and only if $p_{1}$ and $p_{2}$ cannot

Figure 2. An example orientation instance $(T, P)$ with $P=$ $\left\{\left(s_{1}, t_{1}\right),\left(s_{2}, t_{2}\right),\left(s_{3}, t_{3}\right)\right\}$ is shown. The construction from the proof of Lemma 4.1 for the depicted root node $r$ and source-to-target distance 3 partitions $P$ into $P_{0}=\left\{\left(s_{1}, t_{1}\right)\right\}, P_{1}=\emptyset$, and $P_{2}=\left\{\left(s_{2}, t_{2}\right),\left(s_{3}, t_{3}\right)\right\}$. The multiset for a pair $(s, t)$ is chosen with respect to the vertex $v_{(s, t)}$ and its distance from $r$. The distances of the vertices from the root modulo 3 are depicted using different shades of gray.
be satisfied at the same time in any orientation of $T$; equivalently, the path from $s_{1}$ to $t_{1}$ and the path from $s_{2}$ to $t_{2}$ use some edge in different directions. We say that $p_{1}$ and $p_{2}$ are conflicting if there is an edge between them in the conflict graph, and nonconflicting otherwise. Sets of nonconflicting pairs can be satisfied simultaneously, which implies the following fact:

Fact 4.2. Let $(T, P)$ be an orientation instance with a tree $T$. For every $k \in \mathbb{N}$ there exists an orientation of $T$ that satisfies at least $k$ pairs from $P$ if and only if there exists an independent set of size at least $k$ in $C_{(T, P)}$.

Theorem 4.3. Let $d \in \mathbb{N}$. There exists a polynomial-time algorithm that approximates its optimum solution to within a factor of $1 /(2 d)$ for any orientation instance $(T, P)$ in which for every pair the length of the path between the source and the target vertex is at most d.

Proof. Let opt be the size of an optimal solution to MAXIMUM-TREE-ORIENTATION for the given orientation instance $(T, P)$. The algorithm consists of two steps:

First it computes a subset $P^{\prime}$ of the pairs $P$ with $2 \cdot$ opt $/ d \leq\left|P^{\prime}\right|$. Then it computes an orientation $T^{\prime}$ for $T$ satisfying $\left|P^{\prime}\right| / 4$ pairs. As a result, we will satisfy at least OPT/(2d) of the pairs.

For the first step of the algorithm, consider a vertex $r \in V(T)$ and the partition of the pairs $P$ into multisets $P_{0}, \ldots, P_{d-1}$ from the proof of Lemma 4.1. Let $C_{(T, P)}^{\prime}$ be the graph that arises from the conflict graph $C_{(T, P)}$ of $(T, P)$ by deleting all edges between pairs $\left(s_{i}, t_{i}\right)$ and $\left(s_{j}, t_{j}\right)$ with $v_{\left(s_{i}, t_{i}\right)}=v_{\left(s_{j}, t_{j}\right)}$. Two pairs $\left(s_{i}, t_{i}\right)$ and $\left(s_{j}, t_{j}\right)$ from the same set $P_{i}$ have the same vertex $v_{\left(s_{i}, t_{i}\right)}=v_{\left(s_{j}, t_{j}\right)}$ or else their paths do not overlap. Thus, the partition $P_{0}, \ldots, P_{d-1}$ is a valid coloring with $d$ colors of $C_{(s, t)}^{\prime}$. For graphs with colorings of $d$ colors, we can use an algorithm from [Hochbaum 83] that computes an independent set whose size approximates the size of a maximum independent set to within a factor of $2 / d$ in time $O(n m \log n)$, where $n=|P|$ and $m \leq|P|^{2}$ are the numbers of vertices and edges in the considered graph. Let $P^{\prime}$ be such a set for $C_{(s, t)}^{\prime}$. Since $C_{(s, t)}^{\prime}$ is a subgraph of $C_{(s, t)}$, we have $2 \cdot$ OPT $/ d \leq\left|P^{\prime}\right|$.

For the second step consider the partition $P_{0}^{\prime}, \ldots, P_{d-1}^{\prime}$ with $P_{i}^{\prime}=P_{i} \cap P^{\prime}$ of $P^{\prime}$. Similarly to the proof of Lemma 4.1, we compute an orientation that satisfies $1 / 4$ of the pairs for every orientation instance $\left(T, P_{i}^{\prime}\right)$, but this time we are not limited to using only the orientation of a single instance. Since $P^{\prime}$ is an independent set, there are no conflicts between pairs from different sets $P_{i}^{\prime}$ and $P_{j}^{\prime}$. Thus, we are able to merge the orientations for the instances $\left(T, P_{i}^{\prime}\right)$ into an orientation that satisfies at most $1 / 4$ of all pairs from $P^{\prime}$. Altogether, this results in a set of satisfied pairs of size at least OPT/(2d).

## 5. Sublogarithmic Factor Approximation

In this section, we devise a deterministic algorithm that achieves a sublogarithmic approximation guarantee of $\Omega(\log \log n / \log n)$ for MAXIMUM-TREEorientation. Since general instances reduce to tree instances in an approximation-preserving manner, this leads to the same approximation ratio for the general problem maximum-Graph-orientation.

The algorithm first partitions the input pairs $P$ into $\Omega(\log \log n / \log n)$ multisets $P_{i}$. For each orientation instance ( $T, P_{i}$ ), it computes an orientation that satisfies a constant fraction of the optimal number of satisfiable pairs. Consequently, the above-mentioned approximation ratio follows by picking, out of the set of all the computed orientations, the one that satisfies the maximum number of pairs. Below we describe the partition and orientation steps in detail.

## 5.l. Pair Partitioning

The process by which we partition the pairs is a modification of the centroid decomposition used in the proof of Lemma 3.3. Specifically, we will use a decomposition that splits a tree into $k=\lceil\log n\rceil$ subtrees of almost the same size, formalized by the concept of an almost-balanced decomposition: Let $T=(V, E)$ be a tree. An almost-balanced $k$-decomposition of $T$ is a partition of $T$ into $k$ edgedisjoint subtrees $T_{1}, \ldots, T_{k}$ such that each subtree contains between $|E| /(3 k)$ and $3|E| / k$ edges and the number of vertices shared by at least two subtrees is at most $k$. In [Gamzu and Segev 10], the authors showed that for every tree $T$ and integer $k \leq|E(T)|$ there exists an almost-balanced $k$-decomposition for $T$, and that such a decomposition can be computed in polynomial time.

The partition of the pairs corresponds to a recursive decomposition of the input tree $T$. Let $\mathcal{T}_{1}=\left\{T_{1}, \ldots, T_{k}\right\}$ be an almost-balanced $k$-decomposition of $T$. We say that a decomposition separates a pair $\left(s_{i}, t_{i}\right)$ when its end vertices reside in different subtrees of the decomposition (see Figure 3 for an example). The first multiset of pairs, $P_{1}$, consists of all pairs separated by $\mathcal{T}_{1}$. To partition the remaining set of pairs, $P \backslash P_{1}$, we recursively apply the previously described procedure with respect to the collection of subtrees in $\mathcal{T}_{1}$. Specifically, in the second level of the recursion, an almost-balanced $k$-decomposition is computed in each of the subtrees $T_{1}, \ldots, T_{k}$ to obtain a set $\mathcal{T}_{2}$ comprising $k^{2}$ subtrees. The second multiset of pairs, $P_{2}$, consists of all pairs from $P \backslash P_{1}$ that are separated by $\mathcal{I}_{2}$. The remaining multisets $P_{3}, P_{4}, \ldots$ are defined in a similar manner. The recursive process ends as soon as we arrive at a subtree whose number of edges is strictly at most $k$. In this case, we use the decomposition that breaks a tree into its individual edges.
For $k=\lceil\log n\rceil$, the overall number of levels in the recursion, or equivalently, the number of pair multisets, is $O\left(\log _{k} n\right)=O(\log n / \log \log n)$.

### 5.2. A Constant-Factor Approximation for a Single Part

Notice that a multiset of pairs, say $P_{\ell}$, generally consists of several subsets of pairs, each created when different subtrees in $\mathcal{T}_{\ell-1}$ are partitioned by the decomposition $\mathcal{T}_{\ell}$. More specifically, assuming that the subtrees in $\mathcal{T}_{\ell-1}$ are $T_{1}, T_{2}, \ldots$, the class $P_{\ell}$ can be written as the disjoint union of $P_{\ell}^{1}, P_{\ell}^{2}, \ldots$, where $P_{\ell}^{j}$ is the set of pairs that are first separated when $T_{j}$ is partitioned. Recall that the path of any pair separated by some subtree decomposition must be contained in that subtree (otherwise, this pair would have been separated in previous recursion steps). This observation implies that it is sufficient to compute an orientation for a single subtree decomposition and its induced set of separated pairs. Given a

Figure 3. This example shows a tree $T=(V, E)$ with 32 edges and an almostbalanced 7 -decomposition for it. The seven subtrees of the decomposition are highlighted with gray backgrounds; the five border vertices (see below) are filled in black. The number of edges in the subtrees varies between 3 and 7 ; this satisfies the lower bound $|E| / 3 k=32 / 21 \leq 3$ and upper bound $3|E| / k=96 / 7 \geq 7$ for the number of edges that are allowed in the trees of almost-balanced 7 decompositions. The pairs $\left(s_{1}, t_{1}\right)$ and $\left(s_{2}, t_{2}\right)$ are separated by the decomposition, while the pair $\left(s_{3}, t_{3}\right)$ is not separated.
polynomial-time algorithm that computes such an orientation, one can apply it to each of the subtree decompositions in the same recursion level. The resulting orientations of edge-disjoint subtrees define an orientation for the whole input tree, satisfying at least as many pairs as the overall number of pairs satisfied in all individual subtrees.

In what follows, we focus our attention on a single decomposition and devise a randomized algorithm that computes an orientation that satisfies, in expectation, a constant fraction of the optimal number of satisfiable pairs for this decomposition. Formally, an instance of the problem in question consists of a tree $T=(V, E)$ and a partition $\mathcal{T}=\left\{T_{1}, \ldots, T_{k}\right\}$ of this tree into $k$ edge-disjoint subtrees, where $k \leq\lceil\log n\rceil$, and the number of vertices shared by at least two subtrees is less than $k$. In addition, we are given a multiset $P$ of pairs that are separated by the decomposition $\mathcal{T}$.

We need the following notation (exemplified in Figure 4). Let Opt denote the number of satisfied pairs in some fixed optimal orientation of $T$. Let $V_{B} \subseteq V$ be the set of border vertices of $\mathcal{T}$, that is, the set of vertices that are shared by at least two subtrees in $\mathcal{T}$. Moreover, let $S \subseteq T$ be the skeleton of $\mathcal{T}$, namely, the minimal subtree spanned by all border vertices. Note that this subtree consists

Figure 4. An almost-balanced 5-decomposition. Black vertices are border vertices, gray vertices are junction vertices, and the gray areas make up the skeleton of the decomposition.
of the union of paths connecting any two vertices in $V_{B}$. Finally, let $V_{J} \subseteq V$ be the set of junction vertices, defined as nonborder skeleton vertices with degree at least 3 (counting only skeleton edges).

We are now ready to present the orientation algorithm. Our algorithm consists of two phases: segment guessing, in which the optimal direction state of disjoint subpaths of the skeleton is attained, followed by randomized assignment, in which individual edges are assigned a direction.

Segment guessing Let us name the vertex set $V_{B} \cup V_{J}$ the core of the skeleton $S$. One can verify that $\left|V_{B} \cup V_{J}\right|<2 k$, since $\left|V_{J}\right|<\left|V_{B}\right|<k$. We now partition the skeleton into a collection $\Sigma(S)$ of edge-disjoint paths, which are referred to as segments. Each such segment is a subpath of $S$ whose endpoints are core vertices, but its interior traverses only noncore vertices. Clearly, $|\Sigma(S)|=\left|V_{B} \cup V_{J}\right|-1<$ $2 k$.

We now argue that one could obtain in polynomial time the direction state that the optimal orientation induces on each segment $\sigma \in \Sigma(S)$ simultaneously for all segments. To this end, notice that any skeleton segment $\sigma=\left\langle v_{1}, v_{2}, \ldots, v_{\ell}\right\rangle$ may be in one of three possible direction states:

- Right direction: all edges are consistently directed from $v_{1}$ toward $v_{\ell}$, which means that $v_{1} \rightarrow v_{2}, v_{2} \rightarrow v_{3}, \ldots, v_{\ell-1} \rightarrow v_{\ell}$.
- Left direction: all edges are consistently directed from $v_{\ell}$ toward $v_{1}$, namely, $v_{1} \leftarrow v_{2}, v_{2} \leftarrow v_{3}, \ldots, v_{\ell-1} \leftarrow v_{\ell}$.
- Mixed direction: the direction of segment edges is inconsistent.

These definitions imply that the total number of segment direction states to be examined is of polynomial size, since $3^{|\Sigma(S)|}<3^{2 k} \leq 3^{2\lceil\log n\rceil}=O\left(n^{2 \cdot \log 3}\right)$. As a consequence, we may assume without loss of generality that the set of direction

Figure 5. (a) An orientation of a sender subtree, where the thick edges are part of the skeleton. (b) A partition of a pair path into five parts.
states induced by the optimal orientation on all the segments of $\Sigma(S)$ is known in advance. This assumption can be enforced by enumerating over all $O\left(n^{2 \cdot \log 3}\right)$ possible segment direction states.

Randomized assignment. The goal of this phase is to orient the graph while making sure that the edge directions respect the outcome of the segment-guessing phase. For this purpose, we begin by considering skeleton segments that have a consistent direction-namely, segments in either right or left direction states-and assign all the edges in these segments their implied direction. The assignment procedure involves two randomized assignment steps: (1) Each segment in a mixed direction state is assigned, independently and uniformly at random, a right or left direction. All segment edges are oriented according to the chosen direction. (2) Each of the decomposition subtrees $T_{1}, \ldots, T_{k}$ is assigned, independently and uniformly at random, the role of a sender or a receiver. All the nonskeleton edges of each sender subtree are oriented toward the skeleton (in its simplest form, when the subtree contains a single border vertex, all edges are oriented toward that vertex). In contrast, all the nonskeleton edges of each receiver subtree are oriented away from the skeleton. We refer the reader to the example in Figure 5(a).

We turn now to proving that the expected number of satisfied pairs is within a constant factor of optimal, as formally stated in the following claim.

Claim 5.I. The resulting orientation satisfies at least OPT/16 pairs in expectation.

Proof. Recall that we have previously assumed the endpoints of each pair to reside in different subtrees of the decomposition $\mathcal{T}$. In particular, this implies that each pair path must traverse at least one border (core) vertex. For this reason, as
shown in Figure 5(b), we can divide each pair path, with endpoints $s_{i}$ and $t_{i}$, into five (some possibly empty) parts: (1) a subpath between $s_{i}$ and its closest skeleton vertex $v_{s_{i}} ;(2)$ a subpath, along a partial skeleton segment, between $v_{s_{i}}$ and its closest core vertex $r_{s_{i}} ;(3)$ a subpath between $t_{i}$ and its closest skeleton vertex $v_{t_{i}}$; (4) a subpath, along a partial skeleton segment, between $v_{t_{i}}$ and its closest core vertex $r_{t_{i}}$; (5) a subpath between $r_{s_{i}}$ and $r_{t_{i}}$, along a sequence of complete skeleton segments.

With these definitions in mind, let us focus on some pair $\left(s_{i}, t_{i}\right)$ that is satisfied in the optimal orientation. We now argue that with probability at least $1 / 16$, this pair is satisfied in the random orientation constructed by the algorithm. Consequently, by linearity of expectation, the overall expected number of satisfied pairs is OPT/16. The key observation we make to establish this argument is that all the segments along the subpath between $r_{s_{i}}$ and $r_{t_{i}}$ must have a consistent direction in the optimal orientation; otherwise, this pair would not have been satisfied. Accordingly, we may assume that our algorithm assigned the same direction to all the edges in these segments. Now notice that the pair under consideration is satisfied if the following four probabilistic events occur: (1) the edges in the subpath between $s_{i}$ and $v_{s_{i}}$ are oriented toward $v_{s_{i}} ;(2)$ the edges in the subpath between $v_{s_{i}}$ and $r_{s_{i}}$ are oriented toward $r_{s_{i}}$; (3) the edges in the subpath between $v_{t_{i}}$ and $r_{t_{i}}$ are oriented toward $v_{t_{i}}$; and (4) the edges in the subpath between $t_{i}$ and $v_{t_{i}}$ are oriented toward $t_{i}$. One can validate that these four events are independent, and that each one of them occurs with probability of at least $1 / 2$. For example, the edges in the subpath between $s_{i}$ and $v_{s_{i}}$ are oriented toward $v_{s_{i}}$ if the underlying subtree $T_{s_{i}}$ is selected as a sender. As a result, the probability that pair $i$ is satisfied in the random orientation is at least $1 / 16$.

Derandomization. The extent to which we utilize randomization is limited; its purpose is to make the presentation of our algorithm simpler. Each segment in a mixed direction state is randomly assigned one of two possible directions, resulting in at most $2^{|\Sigma(S)|}<2^{2 k} \leq 2^{2\lceil\log n\rceil}=O\left(n^{2}\right)$ possibilities. Each decomposition subtree is randomly assigned one of two possible roles, resulting in at most $2^{k} \leq 2^{\lceil\log n\rceil}=$ $O(n)$ possibilities. To obtain a deterministic polynomial-time algorithm, we can construct the whole space of possible assignments.

In summary, we obtain the following theorem:
Theorem 5.2. There exists a polynomial-time algorithm that approximates MAXIMUM-TREE-ORIENTATION to within a factor of $\Omega(\log \log n / \log n)$ on $n$ vertex trees.

Theorem 5.2 and Lemma 2.2 imply the same approximation bound for the problem on general graphs:

Corollary 5.3. There exists a polynomial-time algorithm that approximates MAXIMUM-GRAPH-ORIENTATION to within a factor of $\Omega(\log \log n / \log n)$ on $n$ vertex graphs.

## 6. Conclusions

In this paper we studied the complexity and approximability of the maximum-GRAPH-ORIENTATION problem. We showed that this problem is NP-hard to approximate to within a factor of $12 / 13$. On the positive side, we provided an $\Omega(\log \log n / \log n)$-approximation algorithm for the problem. In addition, we provided insights into the combinatorial structure of the problem, showing that every orientation instance admits an orientation that satisfies at most $1 /(4\lceil\log n\rceil)$ of its pairs, and that this bound is tight up to a constant factor. We also designed constant-factor approximation algorithms for restricted variants of the problem in which the instance can be decomposed by restricted covers, including star graphs, caterpillars, and graphs in which the distances between the source and target vertices of every pair are bounded.

There are several directions for future research: One direction is to close the gap between our approximation and hardness-of-approximation results. Another direction is to develop algorithms that work on instances in which some of the graph's edges are predirected. This problem is motivated by biological scenarios in which the directions of some of the edges are known, such as for protein-DNA interaction and kinase-substrate interactions. We recently developed a polynomial integer linear programming formulation for the problem and showed that the resulting orientations are much more in line with current biological knowledge compared to orientations that ignore the preset directions [Silverbush et al. 11]. We also proved a sublinear approximation ratio for this problem [Elberfeld et al. 11]. It is open whether this ratio can be improved. A third research direction is to understand the structure of real-world instances and exploit it for algorithms solving the NP-complete orientation problem rapidly in practice. A recent work in this direction, [Dorn et al. 11], determines the values of many structural parameters for different PPI networks and studies the complexity of the orientation problem when parameterized by them.

## 7. Appendix: Proof of Lemma 3.4

Proof. Let $r \in \mathbb{N}$. The orientation instance $\left(T_{r}, P_{r}\right)$ consists of an undirected rooted complete binary tree with depth $r$ and the following multiset of pairs: For every ordered pair $(v, w)$ of distinct leaves in $T_{r}$ we insert $2^{(2 r-d(v, w)) / 2}$ copies of the pair $(v, w)$ into $P_{r}$, where $d(v, w)$ is the distance between $v$ and $w$. Figure 6 shows an example of this orientation instance.
Let $\operatorname{OPT}(r)$ denote the maximum number of satisfied pairs from $P_{r}$ in any orientation of $T_{r}$. Let $\operatorname{OPT}(r, k)$ denote the maximum number of satisfied pairs from $P_{r}$ in orientations for which the root can be reached from exactly $k$ leaves. Due to the definition of the pairs, this is equivalent to saying that there exist exactly $k$ leaves that are reachable from the root: If we flip all edge orientations, then a pair $(v, w)$ is satisfied if and only if the pair $(w, v)$ was satisfied before. Thus, flipping all edge orientations does not change the number of satisfied pairs. By definition, we have $\operatorname{OPT}(r)=\max _{0 \leq k \leq 2^{r}}$ OPT $(r, k)$.

The main technical arguments of this proof are encapsulated in the following claim. For $k \geq 1$, define $g(k)=2^{\lfloor\log k\rfloor}$, the largest power of two that is at most $k$. We claim that for every $r \geq 1$ and $k \geq 0$, we have

$$
o p t(r, k)= \begin{cases}\frac{4^{r}+2 g(k)^{2}}{3}-g(k) k & \text { if } k \geq 1, \\ \frac{4^{r}-4}{3} & \text { if } k=0 .\end{cases}
$$

Once the claim is proven, we know that $\operatorname{OPT}(r, k)$ is maximized for $k=$ 1 , since $\operatorname{OPT}(r, k)$ is monotone decreasing in $k$, starting from $k \geq 1$. Thus $\operatorname{OPT}(r)=\operatorname{OPT}(r, 1)=\left(4^{r}-1\right) / 3$. An example of an optimal orientation for which exactly one leaf has a path to the root is shown in Figure 6(b).

We prove the claim by induction over $r$. For $r=1$, we have $T_{1}=\Omega_{0}^{\text {root }}$, and by checking all four orientations for this tree, we can see that the claim holds for all $k$. We assume that the claim holds for some $r \geq 1$ and all $k$, and prove that is also holds for $r+1$ and all $k$.

Before we proceed with the proof, we will make a short break for a technical observation that is enabled by the induction hypothesis and used later on. We define $(r, k)=\operatorname{OPT}(r, k)-\operatorname{OPT}(r, k+1)$, which is the change of the number of satisfied pairs in optimal orientations if we require that one more leaf has a path to the root. So far, $g(k)$ is defined only for $k \geq 1$. We extend its definition to $g(0)=-1$ and show that $(r, k)=g(k)$ for all $k \geq 0$. For $k=0$, we have

$$
(r, 0)=(r, 0)-(r, 1)=\frac{4^{r}-4}{3}-\frac{4^{r}-1}{3}=-1 .
$$

(b) An optimal orientation $T_{3}^{\prime}$ of $T_{3}$ and the satisfied pairs from $P_{3}$ :

Figure 6. (a) The orientation instance constructed in the proof of Lemma 3.4 is shown for $r=3$. The tree $T_{3}$ is drawn with solid edges; it has $2^{4}-1$ vertices. The pairs from $P_{3}$ are grouped into pairs having the same end vertices (though not necessarily the same source and target vertices); every group is depicted by a gray bidirectional path that connects the two end vertices. The number of ordered combinations of two leaves whose pairs cross the root is $2 \cdot 4^{2} ; 4^{2}$ combinations with first vertex on the left and second vertex on the right side. In $P_{3}$ there is exactly one copy for each of these pairs, and thus the number of pairs in $P_{3}$ that cross the root is $2 \cdot 4^{2}$. All leaf combinations whose pairs do not cross the root but instead cross a vertex one level beneath appear twice in $P_{3}$. In total, the corresponding number of pairs is $2 \cdot 4^{2}$. The same holds if we go down one level further, where all leaf combinations appear four times as pairs in $P_{3}$. In total, the number of pairs in $P_{3}$ is $3 \cdot 2 \cdot 4^{2}$. (b) An optimal orientation $T^{\prime}$ of $T_{r}$ that satisfies $1+4+16=\left(4^{3}-1\right) / 3$ pairs. The pattern of edge orientations in this example (for every vertex, one child edge is oriented upward, and the other child edge is oriented downward) can be generalized to construct optimal orientations for every orientation instance $\left(T_{r}, P_{r}\right)$.

For $k \geq 1$, we consider the equalities

$$
\begin{aligned}
(r, k) & =(r, k)-(r, k+1) \\
& =\frac{4^{r}+2 g(k)^{2}}{3}-g(k) k-\left(\frac{4^{r}+2 g(k+1)^{2}}{3}-g(k+1)(k+1)\right) \\
& =\frac{2}{3}\left(g(k)^{2}-g(k+1)^{2}\right)-g(k) k+g(k+1)(k+1) .
\end{aligned}
$$

If $g(k)=g(k+1)$, which happens if $k+1$ is not a power of 2 , we can derive $(r, k)=g(k)$. If $g(k) \neq g(k+1)$, we know that $g(k+1)=k+1=2 g(k)$ and can extend the equations from above to

$$
\begin{aligned}
(r, k) & =\frac{2}{3}\left(g(k)^{2}-4 g(k)^{2}\right)-g(k) k+4 g(k)^{2}=g(k)(2 g(k)-k) \\
& =g(k)(k+1-k)=g(k)
\end{aligned}
$$

We proceed to prove the claim for $\left(T_{r+1}, P_{r+1}\right)$ and first consider the case $k=0$. The orientations that are possible in this case do not satisfy any of the pairs that cross the root (because there is no path from a leaf to the root). As a result, it suffices to optimally orient the two orientation instances that correspond to the two subtrees beneath the root; they equal $T_{r}$, but with each pair from (the multiset) $P_{r}$ occurring twice. Thus, using the induction hypothesis and the fact that $(r, k)$ is maximized for $k=1$, we can derive $(r+1,0)=2 \cdot 2$. $\max _{0 \leq k \leq 2^{r}}(r, k)=4 \cdot\left(4^{r}-1\right) / 3=\left(4^{r+1}-4\right) / 3$.

Next, we consider $k \geq 1$ and optimal orientations among the orientations for which exactly $k$ leaves have a path to the root. We distinguish two cases: In the first case, both edges incident to the root are directed toward the root, and in the second case, one edge incident to the root is oriented away from the root and the other toward the root.
We start with the first case and consider orientations of the form no pair that crosses the root is satisfied and a total of $k$ leaves have a path to the root, we obtain the equation $(r+1, k)=\max _{0 \leq l \leq k} 2 \cdot(r, l)+2 \cdot(r, k-l)$, where $l$ and $k-l$ are the respective numbers of leaves with paths to the root from the left and right subtrees. Which $l$ maximizes the expression $2 \cdot(r, l)+2 \cdot(r, k-l)$ ? We consider the difference between the expression for two consecutive values of $l$ and derive the following equalities using the induction hypothesis and the technical observation from above:

$$
\begin{aligned}
& 2 \cdot(r, l)+2 \cdot(r, k-l)-(2 \cdot(r, l+1)+2 \cdot(r, k-l-1)) \\
& \quad=2 \cdot(r, l)-2 \cdot(r, k-l-1)=2(g(l)-g(k-l-1))
\end{aligned}
$$

The expression $2(g(l)-g(k-l-1))$ is at most 0 for $l=0$ and at least 0 for $l=k-1$. Moreover, it is monotonically increasing for constant $k$ and increasing
$l$. Thus the smallest value of $l$ for which $2(g(l)-g(k-l-1))$ is at least 0 gives us an $l$ that maximizes $2 \cdot(r, l)+2 \cdot(r, k-l)$. If $k$ is a power of 2 , this happens for $l=k / 2=g(l)$ and implies

$$
(r+1, k)=2 \cdot(r, l)+2 \cdot(r, k-l)=4 \cdot\left(r, \frac{k}{2}\right)=\frac{4^{r+1}+2 g(k)^{2}}{3}-g(k) k
$$

If $k$ is not a power of 2 , which means that $k=2^{t}+d$ for some $t$ and $d$ with $0<d<2^{t}$, it happens for $l=2^{t-1}$ whenever $d<2^{t-1}$, and $d$ whenever $d \geq 2^{t-1}$. Both times we have $g(l)=g(k-l-1)=g(k) / 2$. This implies

$$
\begin{aligned}
(r+1, k)= & 2 \cdot(r, l)+2 \cdot(r, k-l) \\
= & 2 \cdot(r, l)-2 \cdot(r, k-l-1)+2 \cdot(r, k-l-1) \\
= & 2\left(\frac{4^{r}+2 g(l)^{2}}{3}-g(l) l\right)-2 g(k-l-1) \\
& +2\left(\frac{4^{r}+2 g(k-l-1)^{2}}{3}-g(k-l-1)(k-l-1)\right) \\
= & \frac{4^{r+1}}{3}+\frac{8}{3} \frac{g(k)^{2}}{4}-g(k)(l+k-l-1+1)=\frac{4^{r+1}+2 g(k)^{2}}{3}-g(k) k .
\end{aligned}
$$

Now we consider the second case with orientations like can write the optimum as $(r+1, k)=\max _{0 \leq l \leq 2^{r}} 2 \cdot(r, l)+2 \cdot(r, k)+l k$, where $l$ denotes that number of leaves that are reachable from the root in the left subtree. Similarly to the above case, we write down the difference between two subsequent expressions, this time deriving the equation

$$
\begin{aligned}
& 2 \cdot(r, l)+2 \cdot(r, k)+l k-(2 \cdot(r, l+1)+2 \cdot(r, k)+(l+1) k) \\
& \quad=2 \cdot(r, l)-k=2 g(l)-k
\end{aligned}
$$

The expression $2 g(l)-k$ increases with increasing values of $l$ and has its first positive value at $l=g(k)$. This can be used to derive

$$
\begin{aligned}
(r+1, k) & =2 \cdot(r, l)+2 \cdot(r, k)+l k \\
& =2\left(\frac{2^{r}+2 g(k)^{2}}{3}-g(k) k\right)+2\left(\frac{2^{r}+2 g(k)^{2}}{3}-g(k)^{2}\right) \\
& =\frac{4^{r+1}+2 g(k)^{2}}{3}-g(k) k .
\end{aligned}
$$

Taking all steps of the induction proof together proves the claim.
Note that the proved statement also holds if the orientation instance pairs are kept in sets instead of multisets. In this case, we cannot have multiple copies of the same pair, but the proof can be fixed by replacing every leaf with a cycle whose size equals the number of pairs that use the leaf as an end vertex. Then the
pairs are redirected to have unique end vertices. Since for optimal orientations we can restrict to the case that cycles are oriented in a consistent direction, the proof generalizes to this case.
