COMBINATORIAL RICCI FLOWS ON SURFACES

BENNETT CHOW & FENG LUO

Abstract

We show that the analogue of Hamilton's Ricci flow in the combinatorial setting produces solutions which converge exponentially fast to Thurston's circle packing on surfaces. As a consequence, a new proof of Thurston's existence of circle packing theorem is obtained. As another consequence, Ricci flow suggests a new algorithm to find circle packings.

1. Introduction

1.1

For a compact surface with a Riemannian metric (X, g_{ij}), R. Hamilton in [7] introduced the 2-dimensional Ricci flow defined by the equation $\frac{dg_{ij}}{dt} = -2Kg_{ij}$ where K is the Gaussian curvature of the surface. It is proved in [7] and [3] that for any closed surface with any initial Riemannian metric, the solution of the Ricci flow exists for all time, and after normalizing the solution to have a fixed area, the solution converges to a constant curvature metric conformal to the initial metric as time goes to infinity. The purpose of the paper is to study the analogous flow in the combinatorial setting. The simplest case of our setup is as follows. Given a triangulated surface, we assign to each vertex a positive radius and realize the surface by a piecewise flat cone metric with singularities at the vertices where the length of an edge is the sum of the two radii associated to the end points. We call these the (tangential type) circle-packing metrics based on the triangulation. We consider a

---

natural flow (the combinatorial Ricci flow) on the space of all tangen-
tial type circle-packing metrics. Our results give a complete description
of the asymptotic behavior of the solution of the Ricci flow. If we use
hyperbolic geometry as the background metric, then for compact sur-
faces of negative Euler characteristic, we show that the combinatorial
Ricci flow has solutions for all time for any initial metric and converges
exponentially fast to the circle packing metric constructed by Thurston.

1.2

For simplicity, we shall state our results for triangulations on com-
pact surfaces without boundary. For the most general version involving
cellular-decompositions, see §2, §5 and §6.

Suppose X is a closed surface and T is a triangulation on X. Let
$V = \{v_1, v_2, \ldots, v_N\}$ be the set of vertices in T. The set of all edges
and triangles in T are denoted by E and F. Unless mentioned other-
wise a *weight* on the triangulation is a function $\Phi : E \to [0, \pi/2]$. (In
Lemma 2.3, Proposition 3.1 and Proposition 4.1, we allow the weight to
be $\Phi : E \to [0, \pi)$).

Given a weighted triangulation (T, Φ) of a compact surface X, we
consider the circle packing metrics on the surface X based on (T, Φ)
defined as follows.

To each vertex v_i in the triangulation T, assign a positive number
r_i. Now realize each edge e_{ij} joining v_i to v_j by a Euclidean segment of
length

$$l_{ij} = \sqrt{r_i^2 + r_j^2 + 2r_i r_j \cos(\Phi(e_{ij}))}.$$

Note that, due to $\Phi(e) \le \pi/2$, these positive numbers $\{l_{ij}, l_{jk}, l_{ki}\}$ satisfy
triangle inequalities (see [14, Lemma 13.7.2]). (Also note that if the
weight $\Phi = 0$, then $l_{ij} = r_i + r_j$. This corresponds to the case that
circle patterns come from tangency.) Thus we can realize each triangle
$\Delta v_i v_j v_k$ by a Euclidean triangle of edge lengths l_{ij}, l_{jk}, l_{ki}. The triangle
is formed by the centers of three circles of radii r_i, r_j and r_k intersecting
at angles $\Phi(e_{ij}), \Phi(e_{jk})$ and $\Phi(e_{ki})$ where e_{nm} is the edge joining v_n and
v_m. This produces a flat cone metric on the surface X with singularities
at the vertices. We call these metrics the circle-packing metrics (based
on (T, Φ)). Let a_i be the cone angle at the vertex v_i which is the sum
of all inner angles having vertex v_i. The *curvature* K_i at v_i is defined

to be $2\pi - a_i$. The *combinatorial Ricci flow* is the following:

$$(1.1) \qquad\qquad \frac{dr_i}{dt} = -K_i r_i.$$

It is easy to show that for any initial circle-packing metric, the solution of (1.1) with the given initial value exists for all time $t \geq 0$. Our goal is to understand the asymptotic behavior of the solution. To this end, it is useful to consider the normalized Ricci flow,

$$(1.2) \qquad\qquad \frac{dr_i}{dt} = -(K_i - K_{av})r_i$$

where $K_{av} = 1/N \sum_{i=1}^{N} K_i$ is the average curvature. By the Gauss-Bonnet theorem (Proposition 3.1), $K_{av} = 2\pi\chi(X)/N$ is time independent. The two equations (1.1) and (1.2) are related by a change of scales. Namely $r_i(t)$ is a solution to (1.1) if and only if $e^{2\pi t\chi(X)/N}r_i(t)$ is a solution of (1.2). Furthermore, if $r_i(t)$ is a solution to the normalized Equation (1.2), the product $\prod_{i=1}^{N} r_i(t)$ is a constant. For this reason, when we consider the asymptotic behavior of the Ricci flow, it is more convenient to deal with the normalized Ricci flow (1.2). Let $\mathbf{R}_{>0}$ be the set of all positive real numbers.

Definition. A solution to (1.2) is called *convergent* if

(1) $\lim_{t\to\infty} K_i(t) = K_i(\infty) \in (-\infty, 2\pi)$ exists for all i, and

(2) $\lim_{t\to\infty} r_i(t) = r_i(\infty) \in \mathbf{R}_{>0}$ exists for all i.

A convergent solution is called *convergent exponentially fast* if there are positive constants c_1, c_2 so that for all time $t \geq 0$,

$$|K_i(t) - K_i(\infty)| \leq c_1 e^{-c_2 t},$$

and

$$|r_i(t) - r_i(\infty)| \leq c_1 e^{-c_2 t}.$$

Given any subset $I \subset V$, let F_I be the set of all cells in T whose vertices are in I and let the link of I, denoted by $\mathrm{Lk}(I)$, be the set of pairs (e, v) of an edge e and a vertex v so that (1) the end points of e are not in I and (2) the vertex v is in I and (3) e and v form a triangle.

Theorem 1.1. *Suppose (T, Φ) is a weighted triangulation of a closed connected surface X. Given any initial circle-packing metric*

based on the weighted triangulation, the solution to the normalized combinatorial Ricci flow (1.2) in the Euclidean geometry with the given initial value exists for all time and converges if and only if for any proper subset $I \subset V$,

$$(1.3) \qquad 2\pi |I| \chi(X)/|V| > - \sum_{(e,v) \in \mathrm{Lk}(I)} (\pi - \Phi(e)) + 2\pi \chi(F_I).$$

Furthermore, if the solution converges, then it converges exponentially fast to the metric of constant curvature $2\pi \chi(X)/N$.

By the work of Thurston on circle packing, Condition (1.3) is equivalent to the existence of constant curvature circle packing metric based on the weighted triangulation on the surface.

In the case that the surface has negative Euler characteristic, it is natural to replace Euclidean triangles by the hyperbolic ones. The combinatorial Ricci flow in the hyperbolic geometry is the following: Given a surface X with a weighted triangulation (T, Φ) where $\Phi(E) \subset [0, \pi/2]$, we assign to each vertex of T a positive radius r_i. We realize each triangle $\Delta v_i v_j v_k$ by a hyperbolic triangle formed by the centers of three circles of radii r_i, r_j and r_k intersecting at angles $\Phi(e_{ij}), \Phi(e_{jk})$ and $\Phi(e_{ki})$. Let a_i be the cone angle at v_i and $K_i = 2\pi - a_i$ be its curvature. The combinatorial Ricci flow in the hyperbolic metric is,

$$(1.4) \qquad\qquad\qquad \frac{dr_i}{dt} = -K_i \sinh r_i.$$

Theorem 1.2. *Suppose (T, Φ) is a weighted generalized triangulation of a closed connected surface X of negative Euler characteristic. Given any initial choice of circle-packing metric, the solution to (1.4) in the hyperbolic background geometry with the given initial value exists for all time and converges if and only if the following two conditions hold:*

(1.5a) *For any three edges e_1, e_2, e_3 forming a null homotopic loop in X, if $\sum_{i=1}^{3} \Phi(e_i) \geq \pi$, then these three edges form the boundary of a triangle of T.*

(1.5b) *For any four edges e_1, e_2, e_3, e_4 forming a null homotopic loop in X, if $\sum_{i=1}^{4} \Phi(e_i) \geq 2\pi$, then these e_i's form the boundary of the union of two adjacent triangles.*

Furthermore, if it converges, then it converges exponentially fast to a hyperbolic metric on X so that all vertex angles are 2π.

Conditions (1.5a) and (1.5b) were obtained by Thurston in his work on circle packing on surfaces. Indeed, according to [14] Theorem 13.7.1, these two conditions are equivalent to the existence of circle packing metric with curvature equal to zero at each vertex.

The following result shows that Condition (1.3) is almost the same as Conditions (1.5a) and (1.5b) for surfaces with nonnegative Euler characteristic.

Proposition 1.3.

(a) *If the Euler characteristic of the surface X is positive, then Condition (1.3) is valid for all triangulations of X so that there are no null homotopic loops consisting of 3 edges e_1, e_2, e_3 with $\sum_{i=1}^{3} \Phi(e_i) \geq \pi$.*

(b) *If the Euler characteristic of the surface X is zero, then (1.3) is valid for all triangulations of X so that (1.5a) and (1.5b) hold.*

Note that if the weight is the zero function, the conditions in Theorem 1.2 and Proposition 1.3 automatically hold.

1.3

The exponential convergence of the Ricci flow may have some applications in practice. Recall that in his original proof of the existence of zero curvature circle packing metric, Thurston gave an algorithm to find the circle packing. This algorithm adjusts the radii at vertices one at a time. It is shown in [11] that Thurston's algorithm converges in polynomial time to the circle packing. To the best of our knowledge, the existing computer softwares (for instance, [13]) are based on Thurston's algorithm. It seems Ricci flow is more natural and may produce a faster algorithm to find circle packing metrics.

1.4

In the case that the background metric is spherical, we consider triangulations with zero weights. The combinatorial Ricci flow is

$$(1.6) \qquad \frac{dr_i}{dt} = -K_i \sin r_i$$

where we realize each triangle $\Delta v_i v_j v_k$ by a spherical triangle of edge lengths $r_i + r_j, r_j + r_k, r_k + r_i$ (note that we must impose $r_i \in (0, \pi)$ and

$r_i + r_j + r_k < \pi$ in this case). Numerical simulations by L.T. Cheng [2] shows that the situation is very complicated even in the simplest case of triangulations of the 2-sphere, i.e., the boundary of a tetrahedron. For instance, if we start with the boundary of the regular spherical tetrahedron, then the metric will shrink to a point in finite time. If we rescale it to have a fixed area, the cone angles will tend to π (i.e., tends to the boundary of the Euclidean regular tetrahedron if rescaled). But in some other cases, there are initial metrics so that as time goes to a finite number, the metric tends to the round 2-sphere. We do not know what the asymptotic behavior of the solution should be in general.

1.5

The proofs of the above theorems follow the same strategy used by Hamilton in his original approach in the smooth case. Namely, one first derives the evolution equation for the curvature. These equations are essentially of parabolic type. Thus the maximum principle can be applied to control the behaviors of the curvature. In some senses, what we are doing are quantifications of Thurston's original proof. For instance, the fact that the curvature evolution is a heat equation is essentially a consequence of Thurston's lemma 13.7.3 in [14]. We also observed the fact that $\partial\theta_i/\partial r_j \sinh(r_j) = \partial\theta_j/\partial r_i \sinh(r_i)$ (for hyperbolic case) and $\partial\theta_i/\partial r_j r_j = \partial\theta_j/\partial r_i r_i$ (for Euclidean case) where θ_i is the inner angle at i-th vertex corresponding to r_i radius circle (Lemma 2.3). This was first observed in the paper of Colin de Verdiere [5] for the zero weighted triangulation. This makes the Ricci flow variational. Namely, it is essentially a gradient flow of a convex function. We observed that the degeneration condition obtained in Thurston's work implies that the Palais-Smale condition holds for the convex functional. Thus establishes the main results. We remark that the convexity was first observed in [5] in the case of the zero weighted triangulation. Also if a triangulation has zero weight, i.e., $\Phi = 0$, then the convergence part of Theorem 1.2 can also be deduced from the results of Thurston [14] and Colin de Verdiere [5]. Our proofs are different from that of Colin de Verdiere [5]. Colin de Verdiere used a result in network flow to produce the coherent system of angles. From this system, he then produced the convex function and showed that it is proper. In our case, it is the maximum principle and Palais-Smale condition which imply the exponential convergence. Another related work is [1].

1.6

The paper is organized as follows. In §2, we collect some known results concerning triangles. Most of the proofs will be deferred to the appendix. In §3, we derive the evolution equation for the curvature and discuss some of its consequences. In §4, we establish a compactness theorem concerning the solutions of the Ricci flow. In §5, we prove Theorem 1.2. In §6, we prove Theorem 1.1. In the appendix, we derive some basic properties of the triangles.

1.7

2. Preliminaries on triangles

Let K^2 be one of the three geometries, E^2 (Euclidean), S^2 (spherical) and H^2 (hyperbolic), i.e., a simply connected surface with a complete Riemannian metric of curvature equal to 0, 1, and -1. For simplicity, we define a function $s(x)$ according the geometry K^2 as follows. If $K^2 = E^2$, then $s(x) = x$; if $K^2 = H^2$, then $s(x) = \sinh(x)$; and if $K^2 = S^2$, then $s(x) = \sin(x)$.

A function is called *elementary* if it can be obtained from the polynomials, the exponential functions, logarithmic functions, the trigonometric functions and their inverses by the five operations of addition, subtraction, multiplication, division and composition.

2.1

The following lemma of Thurston guarantees the existence of a circle pattern in the geometry K^2.

Lemma 2.1 ([14, Lemma 13.7.2]). *For any three angles Φ_i, Φ_j, $\Phi_k \in [0, \pi/2]$ and any three radii $r_i, r_j, r_k \in \mathbf{R}_{>0}$, there exists a configuration of three circles in both Euclidean and hyperbolic geometries, unique up to isometry, having radii r_i, r_j, r_k and meeting in angles Φ_i, Φ_j, Φ_k. Furthermore, if $r_i + r_j + r_k < \pi$, then such a configuration of three circles also exists in the spherical geometry S^2 and is unique up to isometry.*

Indeed, let x_i be the distance between the centers of the j-th and k-th circles. Then it suffices to verify that $\{x_i, x_j, x_k\}$ satisfies the triangle inequalities that sum of two is larger than the third and also $x_i + x_j + x_k < 2\pi$ in the case of S^2. To see the first, we have $x_i \leq r_j + r_k \leq x_j + x_k$ since $\Phi_n \leq \pi/2$. Furthermore, the equality $x_i = x_j + x_k$ does not hold. The second inequality follows from $x_i + x_j + x_k \leq 2(r_i + r_j + r_k)$.

Consider the triangle formed by the centers of the three circles in Lemma 2.1 in K^2. Let θ_i be the inner angle at the i-th vertex corresponding to the radius r_i circle. Then θ_i is a smooth function of the radii r_i, r_j, r_k. The following is known in Thurston's notes:

Lemma 2.2 ([14, Lemma 13.7.3]). *In all three geometries E^2, H^2 or S^2, if all angles Φ_n's are in $[0, \pi/2]$, then we have:*

(a) $\partial\theta_i/\partial r_i < 0$.

(b) $\partial\theta_i/\partial r_j > 0$ *for* $i \neq j$.

(c) $\partial(\theta_i + \theta_j + \theta_k)/\partial r_i < 0$ *in* H^2, $\partial(\theta_i + \theta_j + \theta_k)/\partial r_i > 0$ *in* S^2 *and* $\partial(\theta_i + \theta_j + \theta_k)/\partial r_i = 0$ *in* E^2.

Furthermore, the partial derivatives $\partial\theta_n/\partial r_m$ are elementary functions in r_i, r_j and r_k where $n, m \in \{i, j, k\}$.

Note part (c) follows from Thurston's geometric argument that the area of the triangle increases when r_i increases. A computational proof of Lemma 2.2 which gives the explicit formulas and the geometric meaning of these partial derivatives can be obtained using Lemma A1 in the Appendix. Also see the proof of Lemma 2.3.

The next lemma was first obtained by Colin de Verdiere [5] in the case where all angles Φ_n's are zero.

Lemma 2.3. *In all three geometries E^2, H^2 and S^2 and for all angles $\Phi_i, \Phi_j, \Phi_k \in [0, \pi)$ so that the triangle of radii r_i, r_j and r_k intersecting at these angles exists,*

$$\partial\theta_i/\partial r_j s(r_j) = \partial\theta_j/\partial r_i s(r_i).$$

We defer the proof to the Appendix. In the Appendix, we give two proofs. The simpler proof uses the mathematical software Maple VII.

One consequence of the lemmas is the following:

Proposition 2.4. *Suppose all angles Φ_n are in $[0, \pi/2]$. If the radii r_n's evolve in time according to some differential equation $dr_n(t)/dt = -K_n s(r_n)$ where K_n is a function of r_i, r_j and r_k and $n = i, j, k$, then the evolution of the inner angle θ_i satisfies the equation,*

$$d\theta_i/dt = -A_{ij}(K_j - K_i) - A_{ik}(K_k - K_i) - A_i K_i \lambda$$

where A_{rs} for $r \neq s$ and A_n are positive valued elementary functions in r_i, r_j and r_k, λ is the curvature of the geometry K^2. Furthermore $A_{rs} = A_{sr}$.

Proof. By the chain rule, we have

$$
\begin{aligned}
d\theta_i/dt &= \partial\theta_i/\partial r_i r_i' + \partial\theta_i/\partial_j r_j' + \partial\theta_i/\partial r_k r_k' \\
&= -\partial\theta_i/\partial r_i s(r_i) K_i - \partial\theta_i/\partial r_j s(r_j) K_j - \partial\theta_i/\partial r_k s(r_k) K_k \\
&= -\partial\theta_i/\partial r_j s(r_j)(K_j - K_i) - \partial\theta_i/\partial r_k s(r_k)(K_k - K_i) - D_i K_i.
\end{aligned}
$$

Here $D_i = \partial\theta_i/\partial r_i s(r_i) + \partial\theta_i/\partial r_j s(r_j) + \partial\theta_i/\partial r_k s(r_k)$. By Lemma 2.3, we can write D_i as $\sum_{l \in \{i,j,k\}} \partial\theta_l/\partial r_i s(r_i) = s(r_i)\partial(\sum_{l \in \{i,j,k\}} \theta_l)/\partial r_i$. By Lemma 2.2(c), the last partial derivative is negative in the case $K^2 = H^2$, is positive in the case $K^2 = S^2$ and is zero if $K^2 = E^2$. Define $A_i = \lambda D_i$ when $K^2 = S^2$ or H^2 and $A_i = 1$ when $K^2 = E^2$. Then $A_i > 0$. Let $A_{mn} = \partial\theta_m/\partial r_n s(r_n)$ for $n \neq m$. Then by Lemma 2.2, it is positive and is an elementary function. Furthermore, the fact $A_{mn} = A_{nm}$ follows from Lemma 2.3. Thus the result follows.

3. The 2-dimensional combinatorial Ricci flow

3.1   Basic setup and the Gauss-Bonnet formula

We set up the Ricci flow in the most general setting as follows.

Suppose X is a connected compact surface with possibly nonempty boundary. A *generalized triangulation* T of X is a cell-division of X into cells so that the lifting of the cell-division in the universal cover is a triangulation. In particular, each 2-cell (triangle) lifts to an embedding in the universal cover and there are no vertices of degree 1 or 2. Also there are no null homotopic loops formed by at most 2 edges. Furthermore, given three vertices, there is at most one triangle having them as vertices. The set of all vertices (0-cells), edges (1-cells) and triangles (2-cells) in T are denoted by V, E, F. Unless mentioned otherwise, a

weight on the generalized triangulation T is a function $\Phi : E \to [0, \pi/2]$. The pair (T, Φ) is called a *weighted* generalized triangulation.

This definition of generalized triangulation is slightly different from Theorem 13.7.1 in Thurston's note. In fact, we were not able to rule out the degree 2 vertices from Thurston's definition. On the other hand, it is clear that if a triangulation is realized by a circle packing, there cannot be any degree two vertices.

Fix a background geometry K^2. Given a compact surface X together with a weighted generalized triangulation (T, Φ), we assign to each vertex $v_i \in V = \{v_1, \ldots, v_N\}$ a positive number r_i. If the geometry K^2 is spherical S^2, we assume that $r_i + r_j + r_k < \pi$ holds for all triples $\{r_i, r_j, r_k\}$ so that the corresponding vertices form a triangle in T.

For each triangle $\Delta v_i v_j v_k$ in F having edges e_{ij}, e_{jk} and e_{ki}, using Lemma 2.1 we can realize the triangle as the one formed by the centers of the three circles of radii r_i, r_j, r_k meeting in angles $\Phi(e_{ij})$, $\Phi(e_{jk})$ and $\Phi(e_{ki})$ in geometry K^2. This produces a Riemannian metric on the surface X of constant curvature having singularities at the vertices. Let a_i be the sum of all inner angles having vertex v_i in triangles. Then the *curvature* at v_i is defined to be $K_i = 2\pi - a_i$ when the vertex v_i is in the interior of X and $K_i = \pi - a_i$ when v_i is in the boundary.

Our first observation is the following:

Proposition 3.1 (Gauss-Bonnet). *Let $\lambda = -1, 0, 1$ be the curvature of one of the three geometries H^2, E^2, S^2 used in the construction. If the circle packing metric based on a weighted generalized triangulation (T, Φ) exists where $\Phi : E \to [0, \pi)$, then the total curvature*

$$\sum_{i=1}^{N} K_i = 2\pi \chi(X) - \lambda \mathrm{Area}\,(X).$$

Note that the three terms in the Gauss-Bonnet formula are additive with respect to gluing along the surface boundary. Thus by doubling the surface X across the boundary if X has nonempty boundary, it suffices to show the result for compact surfaces X without boundary. If X has no boundary, let θ_i^{jk} be the inner angle of the triangle $\Delta v_i v_j v_k$ at v_i (θ_i^{jk} is defined to be zero if v_i, v_j, v_k do not form a triangle). Then the area A_{ijk} of $\Delta v_i v_j v_k$ satisfies the equation,

$$\theta_i^{jk} + \theta_j^{ik} + \theta_k^{ki} = \pi + \lambda A_{ijk}.$$

Since $a_i = \sum_{j,k} \theta_i^{jk}$, we have

$$\sum_i K_i = 2\pi N - \sum_{i,j,k} \theta_i^{jk}$$
$$= 2\pi N - \sum_{\Delta v_i v_j v_k} (\theta_i^{jk} + \theta_j^{ik} + \theta_k^{ki})$$
$$= 2\pi N - \pi|F| - \lambda \mathrm{Area}\,(X)$$
$$= 2\pi \chi(X) - \lambda \mathrm{Area}\,(X).$$

As a consequence, if $K^2 = E^2$, then the average curvature of a circle-packing metric is $2\pi\chi(X)/N$. In particular, the constant curvature metric has curvature $2\pi\chi(X)/N$.

3.2   The combinatorial Ricci flow

We define the combinatorial Ricci flow (with background metric K^2) to be

$$(3.1) \qquad\qquad dr_i(t)/dt = -K_i s(r_i(t)).$$

The evolution of curvature was first obtained by He [9] for zero weighted triangulations in Euclidean geometry.

Proposition 3.2. *Under the Ricci flow* (3.1), *the curvature $K_i(t)$ evolves according to*

$$(3.2) \qquad\qquad dK_i/dt = \sum_{j \sim i} C_{ij}(K_j - K_i) + \lambda B_i K_i$$

where the sum is over all vertices v_j adjacent to v_i, C_{ij} and B_i are positive elementary functions in the radii $r_1, ..., r_N$. Furthermore, $C_{ij} = C_{ji}$.

This is a direct consequence of Proposition 2.4 since

$$dK_i/dt = -\sum_{j,k} d\theta_i^{jk}/dt$$

where θ_i^{jk} are inner angles at v_i in the triangle $\Delta v_i v_j v_k$.

As a consequence, we obtain the maximum principle for curvature evolutions.

Corollary 3.3 (The Maximum Principle). *Let* $r(t) = (r_1(t), \ldots, r_N(t))$ *be a solution of the Ricci flow (3.1) in an interval. Let* $M(t) = \max\{K_1(t), \ldots, K_N(t)\}$ *and* $m(t) = \min\{K_1(t), \ldots, K_N(t)\}$.

(1) *In the case of Euclidean geometry* E^2, *then the function* $M(t)$ *is non-increasing in* t *and* $m(t)$ *is non-decreasing in time* t.

(2) *In the case of hyperbolic geometry* H^2, *then* $\max(M(t), 0)$ *is non-increasing in* t *and* $\min(m(t), 0)$ *is non-decreasing in time* t.

3.3 The long time existence of solutions

As a consequence of the maximum principle, we have,

Proposition 3.4. *Suppose the background geometry* K^2 *is* E^2 *or* H^2. *For any initial metric* $r(0) \in \mathbf{R}_{>0}^N$, *the solution to the Ricci flow (3.1) with the given initial metric exists for all time* $t \geq 0$.

Indeed, we note first of all the curvature K_i is always bounded, i.e.,

$$(2 - d)\pi < K_i < 2\pi$$

where d is the degree of the vertex v_i.

In the case of Euclidean geometry E^2, by (3.1), we obtain

$$c_1 e^{(2-d)\pi t} \leq r_i(t) \leq c_2 e^{2\pi t}$$

for some positive constants c_1 and c_2. Thus $r_i(t)$ remains bounded above and away from zero as long as t is bounded. This implies that the Ricci flow (3.1) has a solution for all time $t \geq 0$ for any initial value $r(0) \in \mathbf{R}_{>0}^N$.

In the case of H^2, since $K_i(t) = d(\ln(\coth(r_i/2)))/dt$, we obtain

$$\coth r_i/2 \leq c e^{2\pi t}$$

where c is some constant. Thus $r_i(t)$ remains bounded away from 0 as long as time t is bounded. On the other hand, the maximum principle (Corollary 3.3) shows that $r_i(t)$ is bounded from above as well. To see this, we first have:

Lemma 3.5. *For any* $\epsilon > 0$, *there exists a number* L *so that when* $r_i > L$, *the inner angle* θ_i *in the hyperbolic triangle* $\Delta v_i v_j v_k$ *is smaller than* ϵ.

This is a simple fact from hyperbolic geometry. Indeed, if we put v_i in the Euclidean center of the disk model for the hyperbolic plane and choose a large radius circle centered at v_i in the hyperbolic space, then the Euclidean diameters of the other two circles centered at v_j and v_k can be made very small. Thus the angle at v_i can be made arbitrary small if the radius r_i is large.

As a consequence of the lemma, if there exists a sequence of times $t_n \to a$ where $a \in (0, \infty]$ so that $r_i(t_n)$ tends to infinity, then $K_i(t_n)$ will tend to 2π. This contradicts the non-increasing property of the function $M(t) < 2\pi$.

By combining the above two, we see that as long as time remains bounded, then $r_i(t)$ and $1/r_i(t)$ remain bounded. This implies that the solution to (3.1) exists for all time $t \geq 0$.

As a consequence of Lemma 3.5 and the maximum principle, we have:

Corollary 3.6. *Suppose $r(t)$ $(t \geq 0)$ is a solution to the Ricci flow (3.1) in hyperbolic background geometry, then there exists a constant C so that $r_i(t) \leq C$ for all time $t \geq 0$ and all indices i.*

3.4 An existence theorem in the hyperbolic and Euclidean cases

The following proposition shows that it suffices to establish a compactness result in order to show the long time convergence of the solution to (3.1).

Proposition 3.7. *Suppose $r(t)$ for $t \in [0, \infty)$ is a solution to the Ricci flow (3.1) in H^2 geometry so that the set $\{r(t)|t \in (0, \infty)\}$ lies in a compact region in $\mathbf{R}^N_{>0}$. Then $r(t)$ converges exponentially fast to a circle packing metric in $\mathbf{R}^N_{>0}$ whose curvature at each vertex is zero.*

Proof. Since the coefficient B_i in (3.2) is an elementary function in $r_1, \ldots, r_N$ and is always positive, it follows from the assumption that there exist two positive constants c_1 and c_2 so that

$$c_1 \leq B_i(r_1(t), \ldots, r_N(t)) \leq c_2$$

for all time $t \geq 0$. Let $M_*(t) = \max(M(t), 0)$ and $m_*(t) = \min(m(t), 0)$. By Equation (3.2), we obtain

$$dM_*(t)/dt \leq -c_1 M_*(t)$$

and
$$dm_*(t)/dt \geq -c_2 m_*(t).$$

Thus there are two constants $c_3 > 0$ and $c_4 > 0$ so that

$$c_5 e^{-c_3 t} \leq m_*(t) \leq M_*(t) \leq c_6 e^{-c_4 t}.$$

This shows that the curvature $K_i(t)$ converges exponentially fast to zero. This in turn implies that $\int_0^t K_i(s)ds$ converges exponentially fast to some constant. Since (3.1) says $\coth(r_i(t)/2) = ce^{\int_0^t K_i(s)ds}$, it follows that $\lim_{t\to\infty} r_i(t) = R_i$ exists in $\mathbf{R}_{>0}$ and $r_i(t)$ converges to R_i exponentially fast. Thus the result follows.   q.e.d.

The same proposition also works for the Euclidean case. In this case, we should normalize the equation. By the Gauss-Bonnet theorem, the sum of the curvatures is $2\pi\chi(X)$. Thus the average curvature K_{av} is $2\pi\chi(X)/N$ which is independent of time t. We define the normalized Ricci flow to be

$$(3.3) \qquad\qquad dr_i(t)/dt = -(K_i - K_{\mathrm{av}})r_i$$

It is easy to verify that $r(t)$ solves (3.3) for $K^2 = E^2$ if and only if $e^{K_{\mathrm{av}}t}r(t)$ solves (3.3).

Proposition 3.8. *Suppose $r(t)$ for $t \in (0,\infty)$ is a solution to the normalized Ricci flow (3.3) in E^2 so that the set $\{r(t)|t \in (0,\infty)\}$ lies in a compact region in $\mathbf{R}_{>0}^N$. Then $r(t)$ converges exponentially fast to a circle packing metric in $\mathbf{R}_{>0}^N$ whose curvature at each vertex is the average curvature K_{av}.*

Proof. To show that the metrics $r(t) = (r_1(t), \ldots, r_N(t))$ converge exponentially to a vector in $\mathbf{R}_{>0}^N$, by the same argument as in the proof of Proposition 3.7, it suffices to show that the curvatures $K(t) = (K_1(t), \ldots, K_N(t))$ converges exponentially fast to $K_{\mathrm{av}}(1, \ldots, 1)$. To this end, let us consider the function $g(t) = \sum_{i=1}^N (K_i(t) - K_{\mathrm{av}})^2$. Since $\sum_{i=1}^N K_i = NK_{\mathrm{av}}$, we have $g(t) = \sum_{i=1}^N K_i^2 - NK_{\mathrm{av}}^2$. Thus the derivative $g'(t) = 2\sum_{i=1}^N K_i(t)K_i'(t)$. By Proposition 2.4 and $dK_{\mathrm{av}}/dt = 0$, the evolution equation for the curvature $K_i(t)$ satisfies the following:

$$K_i'(t) = \sum_{j\sim i} C_{ij}((K_j - K_{\mathrm{av}}) - (K_i - K_{\mathrm{av}}))$$
$$= \sum_{j\sim i} C_{ij}(K_j - K_i),$$

where $C_{ij} = C_{ji}$ is positive and is an elementary function in $r_1, \ldots, r_N$. Thus

$$g'(t) = 2 \sum_{i=1}^{N} \sum_{i \sim j} C_{ij} K_i (K_j - K_i).$$

By switching the order of i, j, we also have

$$g'(t) = 2 \sum_{j=1}^{N} \sum_{j \sim i} C_{ji} K_j (K_i - K_j).$$

Thus

$$(3.4) \qquad g'(t) = -\sum_{i \sim j} C_{ij} (K_i - K_j)^2$$

where the sum is over all pairs of adjacent vertices v_i and v_j. Since the metrics $r(t)$ lies in a compact region in $\mathbf{R}_{>0}^N$, the coefficients $C_{ij}(r_1(t), \ldots, r_N(t))$ remain bounded for all time $t \geq 0$, i.e., $C_{ij} \geq c_1 > 0$ for some constant c_1.

Claim. There exists a constant $c_2 > 0$ depending only on the triangulation T so that

$$c_2 \sum_{i=1}^{N} (K_i - K_{\mathrm{av}})^2 \leq \sum_{i \sim j} C_{ij} (K_i - K_j)^2$$

for all time $t \geq 0$.

Assuming the Claim, by (3.4), we obtain the following:

$$g'(t) \leq -c_2 g(t).$$

This implies that $g(t) \leq c_3 e^{-c_2 t}$ for all time $t \geq 0$ for some constant c_3. In particular, we obtain $|K_i(t) - K_{\mathrm{av}}|^2 \leq g(t) \leq c_3 e^{-c_2 t}$. Thus the proposition holds.

To see the Claim, we first note that since C_{ij} are uniformly bounded from below, it suffices to prove that

$$(3.5) \qquad \sum_{i=1}^{N} (K_i - K_{\mathrm{av}})^2 \leq c_4 \sum_{i \sim j} (K_i - K_j)^2$$

for some constant c_4. By Cauchy's inequality that for any sequence $\{a_i\}$

$$\left(a_i - \frac{\sum_{j=1}^{N} a_j}{N}\right)^2 \leq 1/N \left(\sum_{j=1}^{N}(a_i - a_j)^2\right),$$

we obtain

$$\sum_{i=1}^{N}(K_i - K_{\mathrm{av}})^2 \leq 1/N \sum_{i,j=1}^{N}(K_i - K_j)^2.$$

On the other hand, since the surface X is connected, for any two vertices v_i and v_j in T, there exists a sequence of vertices $v_{m_1} = v_i, v_{m_2}, \ldots, v_{m_l} = v_j$ so that v_{m_h} and $v_{m_{h+1}}$ are adjacent. We can estimate the value $(K_i - K_j)^2$ in terms of the sum of adjacent terms $(K_{m_h} - K_{m_{h+1}})^2$. This shows that there exists a constant c_5 depending only on T so that $(K_i - K_j)^2 \leq c_5 \sum_{l \sim m}(K_l - K_m)^2$. Thus

$$\sum_{i,j=1}^{N}(K_i - K_j)^2 \leq c_5 N \sum_{i \sim j}(K_i - K_j)^2.$$

Combining all these, we establish the claim. Thus the proposition follows.

3.5   The Ricci flow is variational

In this section, we establish the fact that the combinatorial Ricci flow is essentially the gradient flow of a function. In the case that the background geometry is E^2 or H^2, the function is convex.

Let u_i be a function of r_i so that $du_i/dr_i = 1/s(r_i)$. To be more precise, we choose $u_i = \ln r_i$ when $K^2 = E^2$, $u_i = \ln \tanh(r_i/2)$ in $K^2 = H^2$ and $u_i = \ln \tan(r_i/2)$ when $K^2 = S^2$. Let U be the following open set: If $K^2 = E^2$, then $U = \mathbf{R}^N$; if $K^2 = H^2$, then $U = (-\infty, 0)^N$. In the case of the spherical geometry, we take U to be the inverse image of all possible $r = (r_1, \ldots, r_N)$ under the map $(u_1, \ldots, u_N) \to (r_1, \ldots, r_N)$.

Under this change of variable, the Ricci flow (3.1) takes the following form:

(3.6) $du_i/dt = -K_i.$

Indeed, (3.6) is a gradient flow in the variable u. To see this, by Lemma 2.3, we have $\partial K_i/\partial r_j s(r_j) = \partial K_j/\partial r_i s(r_i)$. This is equivalent

to $\partial K_i/\partial u_j = \partial K_j/\partial u_i$. Thus the 1-form $\sum_{i=1}^N K_i du_i$ is closed in the simply connected space U. Define a function $f(u) = \int_a^u \sum_{i=1}^N K_i du_i$ where a is any point in U. Then we have $\partial f(u)/\partial u_i = K_i$. This shows that (3.6) is the negative gradient flow of the function f. We remark that a family of functionals like this f was first constructed by Colin de Verdiere in his paper [5] in the case the weight function is zero. Colin de Verdiere also first proved the convexity of f in the zero weight case.

Proposition 3.9.

(a) *If $K^2 = H^2$, then the function $f(u) : U \to \mathbf{R}$ is strictly convex.*

(b) *If $K^2 = E^2$, then the function $f(u) : U \to \mathbf{R}$ is convex. Furthermore, it satisfies $f(u + a(1, 1, \ldots, 1)) = f(u)$ for all a and f is strictly convex when restricted in the plane*

$$P = \left\{ (u_1, \ldots, u_N) \;\middle|\; \sum_{i=1}^N u_i = 0 \right\}.$$

Proof. Let us consider the hessian of the function f.

Let $a_{ij} = \partial^2 f/\partial u_i \partial u_j = \partial K_i/\partial u_j$. By Lemma 2.2, we have $a_{ii} > 0$ and $a_{ij} \le 0$ ($a_{ij} < 0$ if v_i is adjacent to v_j). Furthermore, Lemmas 2.2 and 2.3 show that if $K^2 = H^2$, then $\partial\theta_i/\partial r_i \sinh(r_i) + \partial\theta_i/\partial r_j \sinh(r_j) + \partial\theta_i/\partial r_k \sinh(r_k) < 0$. Now sum over all such inequalities at the i-th vertex and use the fact that $a_{ij} = -\sum_{r,s} \partial\theta_i^{rs}/\partial r_j \sinh(r_j)$, we obtain $\sum_{j=1}^N a_{ij} > 0$. Recall a simple fact from linear algebra:

Lemma 3.10. *Suppose $A = [a_{ij}]_{n \times n}$ is a symmetric matrix.*

(a) *If $a_{ii} > \sum_{j \ne i} |a_{ij}|$ for all indices i, then A is positive definite*

(b) *If $a_{ii} > 0$ and $a_{ij} \le 0$ for all $i \ne j$ so that $\sum_{i=1}^n a_{ij} = 0$ for all j, then A is semi-positive definite so that its kernel is one-dimensional.*

Thus Part (a) of the proposition follows.

To see Part (b) of the proposition, note that Lemmas 2.2 and 2.3 show that $a_{ii} > 0$, $a_{ij} \le 0$ and $\sum_{i=1}^N a_{ij} = 0$. By the linear algebra fact above, this implies that the matrix $[a_{ij}]$ is semi-definite. Thus f is convex in $\mathbf{R}^n$. The identity $f(u + (a, a, \ldots, a)) = f(u)$ follows from the fact that $K_i(ar) = K_i(r)$. The last fact that $f|_P$ is strictly convex follows from the linear algebra consideration, namely, the kernel of the matrix $[a_{ij}]_{N \times N}$ is generated by the vector $(1, 1, \ldots, 1)$.

To prove Lemma 3.10 (a), it suffices to show that $\det(A) > 0$, since the same argument will show that all determinants of the principle submatrices of A are positive. This in turn implies that A is positive definite. Now to show $\det(A) > 0$, we first show that $\det(A) \neq 0$. This follows easily from the given condition. For instance, if $(x_1, \ldots, x_n)$ were a nonzero vector so that $\sum_j a_{ij} x_j = 0$ for all i, take x_k to be the coordinate with the maximum absolute value. Now consider $\sum_{j=1}^n a_{kj} x_j = 0$. We obtain $a_{kk}|x_k| = |\sum_{i \neq k} a_{ki} x_i|$. But this contradicts the assumptions that $a_{kk} > \sum_{i \neq k} |a_{ki}|$ and $|x_k| \geq \max_i \{|x_i|\}$. Next multiply all off diagonal entries of A by a constant t so that $|t| \leq 1$ to get a new matrix $B(t)$. The matrix $B(t)$ satisfies the same conditions that A satisfies, thus $\det(B(t)) \neq 0$. But $\det(B(0)) > 0$, thus $\det(B(t)) > 0$. In particular $\det(A) = \det(B(1)) > 0$.

To see Part (b) of the lemma, first of all it is clear that $[a_{ij}]$ is semipositive definite (since if we replace a_{ii} by $a_{ii} + s$ for a small positive number s, it becomes positive definite by Part (a)). Thus all eigenvalues of it are nonnegative. Now it is easy to see that the kernel is one-dimensional spanned by $(1, 1, \ldots, 1)$. Thus the result follows.   q.e.d.

Given a smooth strictly convex function defined on an open convex set D, the gradient map sending a point in D to the gradient of f at the point is always injective. Thus as a consequence of the above proposition, we obtained a new proof of the uniqueness part of Thurston's theorem.

Corollary 3.11 ([14]). *Let $\Pi : \mathbf{R}_{>0}^N \to \mathbf{R}^N$ be the map sending a metric $(r_1, \ldots, r_N)$ to the corresponding curvature $(K_1, \ldots, K_N)$ where $K^2 = H^2$ or E^2. Then:*

(a) *In the hyperbolic background geometry, Π is injective, i.e., the metric is determined by its curvature.*

(b) *In the Euclidean geometry, Π restricted to the subset $\{(r_1, \ldots, r_N) \in \mathbf{R}_{>0}^N | \Pi_{i=1}^N r_i = 1\}$ is injective, i.e., the metric is determined by its curvature up to a scalar multiplication.*

4. Degeneration of circle packing metrics

We will recall a related work of [14]. For completeness a slightly different proof is presented. The proof below follows closely [10]. For simplicity, if $I = \{r_j, \ldots r_l\}$ is a subset of vertices V, we will also use I to denote the index set $\{j, \ldots, l\}$.

Proposition 4.1 ([14])**.** *Suppose* (T, Φ) *is a weighted generalized triangulation of a closed surface* X *and* I *is a subset of vertices* V. *Here the weight is a map* $\Phi : E \to [0, \pi)$. *Let* $r^{(n)} = (r_1^{(n)}, \ldots, r_N^{(n)})$ *be a sequence of circle packing metrics based on* (T, Φ) *in background geometry* K^2 *so that* $\lim_{n \to \infty} r_i^{(n)} = 0$ *for* $i \in I$ *and* $\lim_{n \to \infty} r_i^{(n)} > 0$ *for* $i \notin I$. *Then*

$$\lim_{n \to \infty} \sum_{i \in I} K_i(r^{(n)}) = - \sum_{(e,v) \in \mathrm{Lk}(I)} (\pi - \Phi(e)) + 2\pi \chi(F_I),$$

where F_I *is the CW-subcomplex consisting of cells whose vertices are in* I *and* $\mathrm{Lk}(I) = \{(e, v) | e$ *is an edge so that* $e \cap I = \emptyset$ *and the vertex* $v \in I$ *so that* e, v *form a triangle*$\}$.

Furthermore, if the weight $\Phi : E \to [0, \pi/2]$ *and the background geometry is* E^2 *or* H^2, *then for any circle packing metric* r *based on* (T, Φ) *and any proper subset* I *of vertices* V, *we have*

$$\sum_{i \in I} K_i(r) > - \sum_{(e,v) \in \mathrm{Lk}(I)} (\pi - \Phi(e)) + 2\pi \chi(F_I).$$

Proof. Recall that θ_i^{jk} denotes the inner angle at v_i in the triangle $\Delta v_i v_j v_k$. Let $\widetilde{X} \to X$ be the universal cover. Consider triangles in T having a vertex in I. These triangles can be classified into three types A_1, A_2 and A_3 where a triangle Δ is in A_i if and only if a lift of it in the universal cover has exactly i many vertices in $\pi^{-1}(I)$. (Note that in the surface X, there may be triangles having all vertices being v_i.)

Now the curvature $K_i = 2\pi - a_i$ where a_i is the cone angle at v_i. Here $\sum_{i \in I} a_i$ can be written as

$$\sum_{v_i \in I, \Delta v_i v_j v_k \in A_1} \theta_i^{jk} + \sum_{v_i, v_j \in I, \Delta v_i v_j v_k \in A_2} (\theta_i^{jk} + \theta_j^{ik}) + \sum_{\Delta v_i v_j v_k \in A_3} (\theta_i^{jk} + \theta_j^{ik} + \theta_k^{ij}).$$

It is known that as the radius $r_i^{(n)}$ tends to zero, the following hold:

(1) If $\Delta v_i v_j v_k \in A_3$, then $\lim_{n \to \infty} (\theta_i^{jk}(r^{(n)}) + \theta_j^{ik}(r^{(n)}) + \theta_k^{ij}(r^{(n)})) = \pi$. Indeed, the triangle is shrinking to a point in K^2 and thus is becoming a Euclidean triangle.

(2) If $\Delta v_i v_j v_k \in A_2$ and $i, j \in I$, then $\lim_{n \to \infty} (\theta_i^{jk}(r^{(n)}) + \theta_j^{ik}(r^{(n)})) = \pi$. Indeed, the triangle degenerates to a geodesic segment.

(3) If $\Delta v_i v_j v_k \in A_1$ and $i \in I$, then $\lim_{n \to \infty} \theta_i^{jk}(r^{(n)}) = \pi - \Phi(v_j v_k)$ by definition. Here $v_j v_k \in \mathrm{Lk}(I)$.

To summary, we obtain

$$\lim_{n \to \infty} \sum_{i \in I} K_i(r^{(n)}) = - \sum_{(e,v) \in \mathrm{Lk}(I)} (\pi - \Phi(e)) + 2\pi(|I| - 1/2|A_2| - 1/2|A_3|).$$

Here $|A_i|$ denotes the number of triangles of type A_i. Note $|A_3|$ is the number of 2-cells in F_I and $|I|$ is the number of 0-cells in F_I. By the construction, we see that the number of edges in F_I is $1/2(|A_2| + 3|A_3|)$. Thus $|I| - 1/2|A_2| - 1/2|A_3|$ is the Euler characteristic of F_I. This ends the proof.

To see the second part of the proposition, we note that since the background geometry is H^2 or E^2, the sum of the inner angles of a triangle is at most π. Thus, in the first limit (1) above, π is the maximal value. By the same argument, in the second limit (2) above, π is again the maximal value which is never achieved by a nondegenerate triangle. In the third limit (3), since $\Phi(e) \leq \pi/2$, using Lemma 2.1 on the monotonicity, we see that $\pi - \Phi(v_j v_k)$ is also the maximal value for all possible circle packing metrics based on (T, Φ). Furthermore, since $I \neq V$, Cases (2) or (3) do occur. This shows that $- \sum_{(e,v) \in \mathrm{Lk}(I)} (\pi - \Phi(e)) + 2\pi\chi(F_I)$ is strictly less than the sum of the curvature $\sum_{i \in I} K_i(r)$ for any circle packing metric based on (T, Φ).   q.e.d.

Remark. The proof works for all CW-cell decompositions so that each cell has 3 vertices and each vertex has degree at least 2.

Corollary 4.2. *Make the same assumption as in Proposition 4.1 and assume that the weight $\Phi : E \to [0, \pi/2]$. Suppose*

$$- \sum_{(e,v) \in \mathrm{Lk}(I)} (\pi - \Phi(e)) + 2\pi\chi(F_I) > 0.$$

Then one of the following must hold:

(a) *There exists a null homotopic loop consisting of 3 edges e_1, e_2, e_3 so that $\sum_{i=1}^3 \Phi(e_i) > \pi$. Furthermore, if $X \neq S^2$, then these 3 edges do not form the boundary of a triangle.*

(b) *$X = S^2$ and $I = V - \{v\}$ for one vertex v.*

Indeed, choose I' be the nonempty subset of I of the smallest cardinality so that $-\sum_{(e,v)\in\mathrm{Lk}(I)}(\pi-\Phi(e))+2\pi\chi(F_I) > 0$. In this case, $F_{I'}$ is connected since the quantity is additive with respect to connected components of F_I. Thus $\chi(F_{I'}) \leq 1$ so that the equality holds if and only if $F_{I'}$ is contractible. Since $-\sum_{(e,v)\in\mathrm{Lk}(I')}(\pi-\Phi(e)) \leq 0$, we see that $\chi(F_{I'}) = 1$ and $F_{I'}$ is contractible. Let $e_1,\ldots,e_k$ be the set of all edges in $\mathrm{Lk}(I')$. They form a null homotopic loop due to the contractibility of $F_{I'}$. Now if $\mathrm{Lk}(I') \neq \emptyset$, then $\sum_{(e,v)\in\mathrm{Lk}(I')}(\pi-\Phi(e)) \geq k/2\pi$. Thus $k = 3$. Note $k = 1, 2$ are ruled out by the assumption on the generalized triangulation T. If these three edges form the boundary of a triangle, then $F_{I'}$ must be the complement of the triangle. Thus $X = S^2$.

If $\mathrm{Lk}(I') = \emptyset$, then $V - I'$ must consists of vertices so that no two of these vertices are adjacent. On the other hand, $F_{I'}$ is contractible. Thus $V - I'$ consists of only one point. Thus we see that X is a union of two contractible sets and $X = S^2$.

Corollary 4.3. *Make the same assumption as in Proposition* 4.1 *and assume that the weight $\Phi : E \to [0, \pi/2]$. If there are no subsets of V satisfying the condition in Corollary* 4.2 *and if*

$$-\sum_{(e,v)\in\mathrm{Lk}(I)}(\pi-\Phi(e)) + 2\pi\chi(F_I) = 0,$$

then one of the following must hold:

(a) *There exists a null homotopic loop consisting of $k = 3$ or 4 edges $e_1,\ldots,e_k$ so that $\sum_{i=1}^{k}\Phi(e_i) = (k-2)\pi$. Furthermore, if $X \neq S^2$, then these k edges do not form the boundary of a triangle, or union of two adjacent triangles.*

(b) $X = S^2$ *and $I = V - \{v, v'\}$ for two non-adjacent vertices v, v'.*

(c) $X = \mathbf{R}P^2$ *and $I = V - \{v\}$.*

Let I' be the subset of the smallest cardinality so that

$$\sum_{(e,v)\in\mathrm{Lk}(I)}(\pi-\Phi(e)) + 2\pi\chi(F_I) = 0.$$

By the assumption, we conclude that $F_{I'}$ is connected. Thus $\chi(F_{I'}) \leq 1$. By the hypothesis, $\chi(F_{I'}) \geq 0$. If $\chi(F_{I'}) = 1$, then by the given hypothesis, $F_{I'} \neq \emptyset$. By the same argument as above, we obtain conclusion (a). If $\chi(F_I) = 0$, then $\mathrm{Lk}(I') = \emptyset$, i.e., $V - I'$ consists of vertices so that no

two of them are adjacent. But $F_{I'}$ is either the annulus or the Möbuis band. This shows that either $X = S^2$ and $I' = V - \{v, v'\}$ where v, v' are not adjacent or $X = \mathbf{R}P^2$ and $I' = V - \{v\}$.

Corollary 4.4. *Suppose X is a closed surface of negative Euler characteristic and (T, Φ) is a generalized triangulation on X so that the Conditions (1.5a) and (1.5b) in Theorem 1.2 hold. If $r^{(n)} \in \mathbf{R}_{>0}^N$ is a sequence of circle packing metrics in the hyperbolic background metric based on (T, Φ) so that $\liminf_{n \to \infty} K_i(r^{(n)}) \geq 0$ and $\limsup_{n \to \infty} K_i(r^{(n)}) < 2\pi$ for all indices i, then $r^{(n)}$ contains a convergent subsequence in $\mathbf{R}_{>0}^N$.*

Indeed, by Lemma 3.5 and $\limsup_{n \to \infty} K_i(r^{(n)}) < 2\pi$, we see that $r_i^{(n)}$ is bounded from above. To see that $\{r_k^{(n)}\}$ is bounded away from 0, suppose otherwise that it contains a subsequence $\{r_k^{(n_j)}\}$ converging to zero. Let I be the nonempty subset of indices so that $\lim_{j \to \infty} r_i^{(n_j)} = 0$ for $i \in I$ and $\lim_{j \to \infty} r_i^{(n_j)} > 0$ for $i \notin I$. Since $\liminf_{j \to \infty} K_i(r^{(n_j)}) \geq 0$ for all indices i, we obtain $\lim_{j \to \infty} \sum_{i \in I} K_i(r^{(n_j)}) \geq 0$. By Corollaries 4.2 and 4.3, we see that one of the conditions (1.5a), (1.5b) in Theorem 1.2 must be false. This contradicts the assumption.

5. A proof of Theorem 1.2

We will prove the following result which is slightly more general than Theorem 1.2.

Theorem 5.1. *For any weighted generalized triangulation (T, Φ) of a closed connected surface X of negative Euler characteristic and any initial choice of circle-packing metric, the solution to (1.4) with the given initial value exists for all time and converges if and only if the following two conditions hold:*

(1.5a) *For any three edges e_1, e_2, e_3 forming a null homotopic loop in X, if $\sum_{i=1}^3 \Phi(e_i) \geq \pi$, then these three edges form the boundary of a triangle of T.*

(1.5b) *For any four edges e_1, e_2, e_3, e_4 forming a null homotopic loop in X, if $\sum_{i=1}^4 \Phi(e_i) \geq 2\pi$, then these e_i's form the boundary of the union of two adjacent triangles.*

Furthermore, if it converges, then it converges exponentially fast to a hyperbolic metric on X without any singularity.

Note that if the weight Φ is zero, then Conditions (1.5a) and (1.5b) hold automatically. Thus the above result implies the result of Andreev-Koebe-Thurston that for any triangulation of a closed surface of negative Euler characteristic, there exists a hyperbolic metric on the surface and a tangential circle packing in the metric so that the combinatorial pattern of tangency is given by the triangulation.

The proof of the theorem goes in two steps. In the first step, we give a new proof of Thurston's existence of circle packing metric using Ricci flow. This implies that the strictly convex function f whose negative gradient is $du_i/dt = -K_i$ where $u_i = \ln \tanh(r_i/2)$ has a critical point. In particular, this implies that the function f is bounded from below. On the other hand, Corollary 4.4 shows that the function f satisfies the Palais-Smale condition. Thus the negative gradient flow of f converges to the critical point of f. Combining this with Proposition 3.7, we see that all gradient lines converge exponentially fast to the critical point.

5.1

In this subsection, we produce a new proof of the existence of the zero curvature circle packing metric based on the weighted generalized triangulation (T, Φ).

To begin, let us choose the initial metric $r(0) = (r_1(0), \ldots, r_N(0))$ with all $r_i(0)$ sufficiently large so that its curvature at v_i is close to 2π. This is possible by Lemma 3.5. In particular, we have $k_i(0) \geq 0$. Let $r(t) = (r_1(t), \ldots, r_N(t))$ $(t \geq 0)$ be a solution to the Ricci flow (3.1) in H^2 background metric with the initial value $r(0)$. Then by the maximum principle Corollary 3.3, we have $k_i(t) \geq 0$ for all time $t \geq 0$. On the other hand, by the maximum principle again we have $\limsup_{t \to \infty} k_i(t) < 2\pi$. Thus by Corollary 4.4, we see that the set $\{r(t) | t \in [0, \infty)\}$ lies in a compact region in $\mathbf{R}_{>0}^N$. Thus by Proposition 3.7, the solution $r(t)$ converges exponentially fast to the zero curvature metric. In particular, this shows the zero curvature metric exists.

5.2

To show the convergence of the Ricci flow (3.1) in H^2 background metric in the general case, we use the result in Subsection 3.5. Recall that if we consider the change of variable $u_i = \ln \tanh(r_i/2)$, then the Ricci flow becomes $du_i/dt = -K_i$ which is proved to be a negative gradient

flow. Let f be a potential function. It is known by Proposition 3.9 that the function f is strictly convex defined on $(-\infty, 0)^N$. We claim that f satisfies the Palais-Smale condition. As a consequence, we see all gradient lines converge to the critical point. Thus the result follows.

To verify the Palais-Smale condition, first of all by §5.1, we see that f has a critical point which must be the minimal point due to the convexity. Thus f is bounded from below. To verify the second condition in Palais-Smale, take a sequence of points $\{u^{(n)}\}$ in $(-\infty, 0)^N$ so that the gradient of f at $u^{(n)}$ converges to zero. Let the corresponding points of $u^{(n)}$ be $r^{(n)} \in \mathbf{R}_{>0}^N$. Then we have that the curvature $K_i(r^{(n)})$ tends to zero for all indices i as n tends to infinity. By Corollary 4.4, this implies that the set $\{r^{(n)} | n \in \mathbf{Z}_{>0}\}$ lies in a compact set. This in turn implies that $\{u^{(n)}\}$ contains a convergent subsequence in $(-\infty, 0)^N$. This ends the proof.

Finally the necessity of Conditions (1.5a) and (1.5b) which was proved in [14] follows from Proposition 4.1. Indeed, since the zero curvature metric exists, we conclude that for any subset $I \in V$, the quantity $-\sum_{(e,v)\in \mathrm{Lk}(I)}(\pi - \Phi(e)) + 2\pi\chi(F_I) < 0$. On the other hand, if (1.5a) or (1.5b) is false, then take I to be the vertices in the disk bounded by the null homotopic loop formed by the edges. We see that $-\sum_{(e,v)\in \mathrm{Lk}(I)}(\pi - \Phi(e)) + 2\pi(\chi(F_I)) \geq 0$.

Remark 5.3. The proof in fact shows the following for a generalization of the Ricci flow in hyperbolic background metric. Namely, suppose there exists a circle packing metric R so that its curvature is C_i at the i-th vertex. Then the following flow $dr_i/dt = -(K_i - C_i)\sinh(r_i)$ has a solution for all time $t \geq 0$ for all initial metrics and the solution converges exponentially fast to R.

6. A proof of Theorem 1.1 and Proposition 1.3

We will prove the following theorem for generalized triangulations which implies Theorem 1.1.

Theorem 6.1. *For any weighted generalized triangulation T of a closed connected surface X and for any initial circle-packing metric based on the weighted triangulation, the solution to the normalized combinatorial Ricci flow (1.2) in Euclidean background metric with the given*

initial value converges if and only if for any proper subset $I \subset V$,

$$(1.3) \qquad 2\pi\chi(X)|I|/N > - \sum_{(e,v)\in\mathrm{Lk}(I)} (\pi - \Phi(e)) + 2\pi\chi(F_I).$$

Furthermore, if the solution converges, it converges exponentially fast to the metric of constant curvature $2\pi\chi(X)/N$.

The proof is essentially the same as in §5 and goes in two steps. In the first step, we show that the constant curvature circle packing metric exists due to Condition (1.3). Next we show that the normalized Ricci flow is the negative gradient flow of a convex function in the variable $u_i = \ln r_i$ and that the function f satisfies the Palais-Smale condition. Combining this with Proposition 3.7, we see that all gradient lines converge exponentially fast to the critical point.

6.1

In this subsection, we produce a proof of the existence of the constant curvature circle packing metric based on the weighted generalized triangulation (T, Φ) under Condition (1.3). This result is implicitly in [14]. Our proof follows the work [10]. Let P be the set $\{r = (r_1, \ldots, r_N) \in \mathbf{R}^N_{>0} | \prod_{i=1}^N r_i = 1\}$. Consider the curvature map $\Pi : P \to \mathbf{R}^N$ sending the metric r to its curvature $\Pi(r) = (K_1(r), \ldots, K_N(r))$. By Corollary 3.11, it is injective. Furthermore, by Gauss-Bonnet, its image lies in the hyperplane defined by the equation $\sum_{i=1}^N K_i = 2\pi\chi(X)$. Consider the convex polytope Y in the hyperplane defined by the set of all linear inequalities $\sum_{i\in I} K_i > - \sum_{i\in I}(\pi - \Phi(e)) + 2\pi\chi(F_I)$ where I is a proper subset of vertices. Then by Proposition 4.1 the map $\Pi : P \to Y$ sends compact sets to compact sets. Since both P and Y are homeomorphic to $\mathbf{R}^{N-1}$, by the invariance of domain theorem, the map $\Pi : P \to Y$ is a homeomorphism. In particular, we see that the constant curvature metric exists if and only if (1.3) holds for all proper subsets I of V.

6.2

To show the convergence of the Ricci flow for all initial choice of metrics, let us take $u_i = \ln r_i$. Then the normalized Ricci flow becomes $du_i/dt = -(K_i - K_{\mathrm{av}})$. This later equation is the negative gradient flow of a convex function $f(u)$ defined on the u-space $\mathbf{R}^N$. Furthermore, if we restrict to the subspace $Z = \{u = (u_1, \ldots, u_N) \in \mathbf{R}^N | \sum_{i=1}^N u_i = 0\}$,

the function f is strictly convex Proposition 3.8. By the result in Subsection 6.1, we see that f has a critical point. Thus it is bounded from below. We claim that f satisfies the Palais-Smale condition on the plane Z. To this end, take a sequence of vectors $u^{(n)}$ in Z so that the gradient of f at $u^{(n)}$ tends to zero. Let $r^{(n)}$ be the corresponding points in the space P. Then $\lim_{n\to\infty} K_i(r^{(n)}) = K_{\mathrm{av}}$ for all indices i. By the assumption that $K_{\mathrm{av}}(1,\ldots,1)$ lies in the open cell $\Pi(P)$, we see that $r^{(n)}$ lies in a compact set in P. Thus $\{u^{(n)}\}$ contains a convergent subsequence. This shows all gradient lines converge to the constant curvature metric. Thus by Proposition 3.7, the solution $r(t)$ converges exponentially fast to the constant curvature metric.

6.3

The proof in fact shows the following for a generalization of the Ricci flow in Euclidean background metric. Namely, suppose there exists a circle packing metric R so that its curvature is C_i at the i-th vertex. Then the following flow $dr_i/dt = -(K_i - C_i)r_i$ has a solution for all time $t \geq 0$ for all initial metrics and the solution converges exponentially fast to R.

6.4   A proof of Proposition 1.3

Proposition 1.3.

(a) *If the Euler characteristic of the surface X is positive, then Condition (1.3) is valid for all generalized triangulations of X so that there are no null homotopic loops consisting of 3 edges $e_1,\ldots,e_3$ so that $\sum_{i=1}^{k} \Phi(e_i) \geq \pi$.*

(b) *If the Euler characteristic of the surface X is zero, then (1.3) is valid for all triangulations of X so that (1.5a) and (1.5b) hold.*

This follows from Corollaries 4.2 and 4.3.

7. Some questions

There are several questions which we find interesting relating to the results in the paper.

1. *Generalizing Lemma* 2.2. It can be shown that Lemma 2.2 is false if the assumption $\Phi_i \in [0, \pi/2]$ is relaxed to Φ_i's in $[0, \pi)$. In fact there exists a choice of $\Phi_n \in [0, \pi)$ so that $\partial\theta_i/\partial r_i < 0$. But on the other hand, it seems for applications, the convexity of the function f in Proposition 3.9 is essential. Thus the question is for what choices of Φ_n's in $[0, \pi)$ is the matrix $[s(r_j)\partial\theta_i/\partial r_j]_{3\times 3}$ positive or semi-positive definite.

2. 2-*dimensional combinatorial Ricci flow for all piecewise constant curvature metrics.* Hamilton's Ricci flow works for all Riemannian metrics. Fix a triangulation on a surface, the analog of Riemannian metric seems to be the piecewise constant curvature metric obtained by assigning lengths to each edge in the triangulation. Is there any Ricci flow defined on the space of all these metrics? This may have some applications to the problems like, what is the space of all geometric triangulations of a triangle with the fixed combinatorial data.

3. Investigate the 2-dimensional combinatorial Ricci flow in Theorems 1.1 and 1.2 so that the combinatorial conditions (1.3) and (1.5a) and (1.5b) are not valid. The solution still exists for all time $t \geq 0$. Is it true that for any solution $r(t) = (r_1(t), \ldots, r_N(t))$ where $t \geq 0$, the limit $\lim_{t\to\infty} r_i(t)$ always exists in the extended set $[0, \infty]$?

   In the case of the Euclidean background metric, for negative Euler characteristic closed surfaces, if $r(t)$ with $t \geq 0$ is a solution to the Ricci flow (1.3), is it true that the metric $r(t)$ will have nonpositive curvature when t is large?

4. Investigate the 2-dimensional combinatorial Ricci flow in the case that the weight is in $[0, \pi)$. For instance, can one produce a new proof of the results of Igor Rivin [12] using heat equations?

5. We showed that rigidity of the circle packing follows from the strictly convexity of the potential function in this paper (Corollary 3.11). The convexity is based on the main technical Lemma 2.3. Derive the main result of He [9] on the rigidity of locally finite infinite circle packings from the convexity of the potential function.

6. Is there any 3-dimensional combinatorial analogous of Hamilton's 3-dimensional Ricci flow [8]?

The recent work of David Glickenstein's UCSD thesis ([6]) seems to indicate that the analog of the Yamabe flow exists in the combinatorial setting in dimension 3 (see also [4]).

Appendix. Some computations involving triangles

A1. Basic results on triangles

Given a triangle $\Delta v_i v_j v_k$ in one of the three geometries $K^2 = S^2, E^2$ and H^2, let the inner angle at the v_i vertex be θ_i and the length of the edge $v_j v_k$ be x_i. Recall that the function $s(x)$ is defined according to the geometry K^2 as follows: $s(x) = x$ for E^2, $s(x) = \sin(x)$ for S^2 and $s(x) = \sinh(x)$ for H^2. Let $A_{ijk} = s(x_i)s(x_j)\sin(\theta_k)$. By the sine law, the quantity A_{ijk} is symmetric in i, j, k. The following is a very useful lemma for computing derivatives:

Lemma A1. *In all three geometries we have:*

(a) $\partial\theta_i/\partial x_i = s(x_i)/A_{ijk}$.

(b) $\partial\theta_i/\partial x_j = -\partial\theta_i/\partial x_i \cos(\theta_k)$.

(c) $\partial\theta_i/\partial x_j s(x_j)$ *is symmetric in i, j.*

(d) *Consider x_k as a function of x_i, x_j, θ_k. Then*

$$\partial x_k/\partial x_i = \cos(\theta_j).$$

The proof is a simple application of the cosine law. We will omit the details. It is interesting to note that these derivatives formulas are the same for all three geometries.

One interesting consequence of Lemma A1(c) is the following:

Corollary A2. *For any triangle in the geometry K^2, the 1-form $\sum_{l \in \{i,j,k\}} \theta_l s(x_l)dx_l$ in variables x_i, x_j, x_k is closed.*

A2. A proof of Lemma 2.3

A simpler proof using mathematical software Maple VII is given in the next subsection. In this subsection, we present a conventional proof.

Suppose we have a collection of three closed disks C_i, C_j, and C_k centered at v_i, v_j and v_k so that their radii are r_i, r_j and r_k and their exterior intersection angles are $\phi_i, \phi_j, \phi_k \in [0, \pi)$ in geometry K^2. Consider the triangle formed by v_i, v_j, v_k. Let its inner angle at v_n be θ_n and the edge length opposite to v_n be x_n. We want to show that $\partial \theta_i / \partial r_j s(r_j)$ is symmetric in i, j.

First of all if L_i, L_j and L_k are the geodesic lines passing through the pairs of the intersection points of $\{C_k, C_j\}$, $\{C_k, C_i\}$ and $\{C_i, C_j\}$ (L_i is the tangent to C_j and C_k if they intersect in one point), then the three lines L_i, L_j, L_k intersect in one point.

To see this, we note that the result is well-known in the Euclidean geometry E^2. To see the result in hyperbolic geometry, let O be the point of intersection of L_i and L_j. Take the disk model for H^2 so that O is the Euclidean center. Then both L_i and L_j are Euclidean line segments. Let L'_k be the Euclidean diameter passing through O and one of the intersection point of C_i with C_j. The by the result in the Euclidean case, we see that L_k must contain the other point of intersection of C_i and C_j. This shows, $L'_k = L_k$. The same argument also works for the spherical case where we consider the stereographic projection from the antipodal point of O. Let u_r be an intersection point of the circles C_s and C_t where $\{r, s, t\} = \{i, j, k\}$.

To begin the proof, by Lemma A1, we have

$$s(r_j)\partial\theta_i/\partial r_j = s(r_j)(\partial\theta_i/\partial x_i \partial x_i/\partial r_j + \partial\theta_i/\partial x_k \partial x_k/\partial r_j)$$
$$= s(r_j)\partial\theta_i/\partial x_i(\partial x_i/\partial r_j - \cos(\theta_j)\partial x_k/\partial r_j)$$
$$= \frac{s(x_i)\sin(\theta_j)}{A_{ijk}} \frac{s(r_j)(\cos(\theta_j^{ki'}) - \cos(\theta_j)\cos(\theta_j^{ik'}))}{\sin(\theta_j)}.$$

Here $\theta_j^{ik'}$ and $\theta_j^{ki'}$ are the inner angles at v_j in the triangles $\Delta v_j v_i u_k$ and $\Delta v_j v_k u_i$. Note that the first fraction $s(x_i)\sin(\theta_j)/A_{ijk}$ is symmetric in i, j due to the sine law. Thus it suffices to show that

$$\frac{s(r_j)(\cos(\theta_j^{ki'}) - \cos(\theta_j)\cos(\theta_j^{ik'}))}{\sin(\theta_j)}$$

is symmetric in i, j.

To this end, we will need the following lemma about quadrilaterals in K^2 so that two opposite angles are right angles.

Lemma A3. *Suppose Q is an immersed quadrilateral in geometry K^2 so that its four edges are T, X, Y, Z counted clockwise. Suppose*

the inner angle between sides $\{T, X\}$ and $\{Y, Z\}$ are right angles and the inner angle between sides $\{X, Y\}$ is θ, and edges T, Y are disjoint. Let the lengths of sides X, Y, Z be x, y, z and t be the length of T if $X \cap Z = \emptyset$ and t be the negative of the length of T if X intersects Z. Then the following hold:

(a) *In the Euclidean geometry E^2,*

$$t = (y - x \cos \theta)/\sin \theta.$$

(b) *In the hyperbolic geometry H^2,*

$$\tanh(t) = \cosh(x)(\tanh(y) - \tanh(x) \cos(\theta))/\sin(\theta).$$

(c) *In the spherical geometry S^2,*

$$\tan(t) = \cos(x)(\tan(y) - \tan(x) \cos(\theta))/\sin(\theta).$$

The proof is a direct application of trigonometries for right angled triangles and quadrilaterals with three right angles. (See for instance [15].)

Another simple fact we shall use is the following formulas for right angled triangles. Suppose a right angled triangle has three edge lengths a, b, c and whose opposite angles are α, β and $\pi/2$. Then we have, $\cos(\alpha) = b/c$ in E^2, $\cos(\alpha) = \tanh(b)/\tanh(c)$ in H^2, and $\cos(\alpha) = \tan(b)/\tan(c)$ in S^2.

Let the distance from the common intersection O to the intersection point of the lines L_k and $v_i v_j$ be d. Let D be d if O is inside the triangle and $-d$ otherwise. It is symmetric in i, j. Then by the above lemma and the trigonometric formulas, we obtain that the expression $s(r_j)(\cos(\theta_j^{ki'}) - \cos(\theta_j) \cos(\theta_j^{ik'}))/\sin(\theta_j)$ is equal to the D, $\tanh(D)$ and $\tan(D)$ respectively. This verifies the symmetry. Note that if all angles Φ_i's are in $[0, \pi/2]$, then the common intersection point O is inside the triangle. Thus $d > 0$ which is what Lemma 2.2(b) states.

A3. A proof of Lemma 2.3 using Maple VII

The simplest proof of the lemma is to use some mathematical software so that we do not have to go over all possible configurations. We will present such a proof using Maple VII below.

Let T_3 be the space of all possible configurations of pairwise inter-secting three circles in K^2 up to isometry so that their centers form a triangle. The we claim that T_3 is connected. To see this, since the space of all triangles up to isometry is connected, it suffices to show that the subspace of all pairwise intersecting three circles with fixed centers is connected. To see the later space, let us exam the three radii. We can choose the radius of the first circle arbitrary as long as it lies in its natural interval (e.g, it is $(0, \infty)$ for E^2 and H^2, and is $(0, \pi/2)$ for S^2). Now the radius of the second circle must also be in an interval since it intersects the first circle. The radius of the third must be in an interval as well since it intersects the first and the second circle and these two circles intersect. This shows that the space is connected.

Now to show $\partial\theta_i/\partial r_j s(r_j)$ is symmetric in i, j, it is much convenient for the machine to verify that $(\partial\theta_i/\partial r_j s(r_j))^2$ is symmetric in i, j. On the other hand, both functions $\partial\theta_i/\partial r_j s(r_j)$ and $\partial\theta_j/\partial r_i s(r_i)$ are ana-lytic in variables $\Phi_i, \Phi_j, \Phi_k, r_i, r_j, r_k$ and defined on a connected space so that they coincide in the subspace $r_i = r_j$. Thus $\partial\theta_i/\partial r_j s(r_j)$ must be symmetric in i, j if its square is symmetric.

To verify the symmetry of $((\partial\theta_i/\partial r_j)r_j)^2$ in i, j for Euclidean geom-etry E^2 using Maple VII, we run the following:

```
> yi := sqrt (rj^2 + rk^2 + 2 * rj * rk * bi);
> yj := sqrt (ri^2 + rk^2 + 2 * ri * rk * bj);
> yk := sqrt(rj^2 + ri^2 + 2 * rj * ri * bk);
> ai := arccos(((yj)^2 + (yk)^2 − (yi)^2)/(2 * (yj) * (yk)));
> fij := diff (ai, rj) * rj;
> g1 := simplify (fij);
> g2 := g1^2;
> g3 := subs ({ri = rj, rj = ri, bi = bj, bj = bi}, g2) − g2;
> simplify (g3);       0
```

To verify the symmetry of $((\partial\theta_i/\partial r_j)\sinh(r_j))^2$ in i, j for hyperbolic geometry H^2 using Maple VII, we run the following:

```
> yi := arccosh (cosh(rj) * cosh(rk) + sinh(rj) * sinh(rk) * bi);
> yj := arccosh (cosh(rk) * cosh(ri) + sinh(ri) * sinh(rk) * bj);
> yk := arccosh (cosh(rj) * cosh(ri) + sinh(rj) * sinh(ri) * bk);
> ai := arccos((cosh(yj)*cosh(yk)−cosh(yi))/(sinh(yj)*sinh(yk)));
> fij := diff (ai, rj) * sinh(rj);
> g1 := simplify (fij);
> g2 := g1^2;
```

> $g3 := \text{subs}(\{ri = rj, rj = ri, bi = bj, bj = bi\}, g2) - g2;$
> $\text{simplify}(g3);$ 0

To verify the symmetry of $((\partial\theta_i/\partial r_j)r_j)^2$ in i, j for spherical geometry S^2 using Maple VII, we run the following:

> $yi := \arccos(\cos(rj) * \cos(rk) + \sin(rj) * \sin(rk) * bi);$
> $yj := \arccos(\cos(rk) * \cos(ri) + \sin(ri) * \sin(rk) * bj);$
> $yk := \arccos(\cos(rj) * \cos(ri) + \sin(rj) * \sin(ri) * bk);$
> $ai := \arccos((-\cos(yj) * \cos(yk) + \cos(yi))/(\sin(yj) * \sin(yk)));$
> $fij := \text{diff}(ai, rj) * \sin(rj);$
> $g1 := \text{simplify}(fij);$
> $g2 := g1^2;$
> $g3 := \text{subs}(\{ri = rj, rj = ri, bi = bj, bj = bi\}, g2) - g2;$
> $\text{simplify}(g3);$ 0

This ends the proof.
